Exploring nanopore long reads and whole-genome sequencing data to characterize long tandem repeats and chromosome structure in mammalian genomes

Daniel Alexandre Varela Marques Eleutério

Mestrado em Bioquímica e Biomedicina

Dissertação orientada por:
Professora Doutora Margarida Gama Carvalho
Doutor Ricardo Dias

2023

Acknowledgements

First and most notably I want to thank my professor Margarida Gama Carvalho for her great patience and dedication in dealing with me through all these years.

I also want to thank Mariana Lopes, Sandra Louzada and Raquel Chaves from the CytoGenomics Lab (UTAD) for providing me with the opportunity to participate in the project regarding the HSat1A study. This project also led to a scientific publication, indicated in reference: (Lopes et al., 2023).

I want to thank Mariana Nascimento and Ricardo Dias for supplying their time and effort in teaching me to use Nanopore sequencing technology.

Big thanks to all the people in the RNA Systems Biology group that helped me with the little and big questions, shared their compassion and knowledge.

Thank you to some of my friends that always provided me with care and attention: Raquel Teixeira, for sharing some of the wildest stories out there; Noémi Velez, for being my “comadre”; André Salvada, for your compassion and care of both my mental and physical health; Afonso Bravo, for providing a great guidance into the future; Diogo Tomaz, for your compliance with the weirdness and impartial outlook on life; Nuno Ribeiro and João Raposo, for being my great childhood friends, and I hope that I can make you proud.

Special thank you to Larissa Godoi, for loving me through this crazy and long journey.

Lastly and most importantly, I want to thank my father, my mother and sister, that always supported, cared for, provided, and loved me through all these years, and that helped me reach my goal. Thank you so much.

Abstract

Long tandem repeats (LTRs) sequences, namely satellite DNA (satDNA), play a critical role in genome organization and stability. Their detection and characterization still represent a challenge, which long-read Nanopore sequencing is helping to simplify. Thus, there is a growing interest in developing bioinformatic tools for the analysis of LTRs and in understanding their role in genome evolution. The main aim of this work was the characterization of LTRs in mammalian genomes, using WGS data from two model organisms: *Peromyscus* genus and *Homo sapiens*. In the first case, the focus was to characterize PMSat, an evolutionarily conserved satDNA. In the second case, the key objective was to perform a comparative assessment of LTRs between different human long-read genome datasets, to characterize in detail the human satellite HSat1A and its transcripts, and to establish methods to analyze satDNA involvement in Robertsonian translocations (specifically the t(14;21)).

The analysis performed identified PMSat as the most abundant LTR of the *Peromyscus* genus, in accordance with previous cytogenetic studies, with GC-content, monomer and array length exhibiting little variation. Moreover, a tendency in the positioning in *Peromyscus* genus chromosomes was identified. In the study of the three WGS Nanopore human datasets, the LTRs ALR, BSR, HSat2 and HSat1A were identified as the most abundant. It was possible to demonstrate the potential of chromosome sorting to facilitate the analysis of translocated chromosomes. However, low sequencing yield and DNA fragmentation did not allow for characterization of the target region. Finally, LTRs of HSat1A were shown to have a predominance of 9-mer monomers, and to express polyadenylated transcripts of varying lengths, probably resulting from alternative polyadenylation.

This study represents a relevant contribution to understanding the role of LTRs in genome organization and evolution.

Keywords: LTR; satellite DNA; Nanopore sequencing; PMSat; HSat1A.

Resumo Alargado

Sequências repetitivas encontradas em regiões peri/centroméricas têm demonstrado um papel crucial na organização e estabilidade genómica. Estas regiões são compostas por repetições longas em tandem (LTRs). Incluídas neste grupo estão os DNA satélite (satDNA), que são caracterizados por montagens de matrizes de sequências repetitivas de cabeça-a-cauda. PMSat, um satDNA presente no género *Peromyscus*, embora demonstrando variação do número de cópias e localização, preserva a sequência e estrutura, desafiando as previsões de impulso molecular. Portanto, este género demonstrou um grande potencial para o estudo de LTRs em regiões peri/centroméricas, pois as espécies deste género demonstram ter rearranjos cromossómicos enquanto mantêm um número estável de 48 cromossomas.

No genoma humano existem várias famílias de DNA satélite humano, que são compostas por uma grande variedade de populações e qualidades. Embora existam estratégias recorrentes para detecção e caracterização de LTRs, nomeadamente satDNA, estas são baseadas em digestão de DNA genómico com endonucleases de restrição, seguida de análise de sequências de monómeros ou multímeros curtos aleatoriamente clonados. Isto dificulta a análise destes elementos repetitivos devido às suas curtas dimensões. No entanto, novas tecnologias de sequenciação (NGS) têm emergindo, como a tecnologia de sequenciação por nanoporos, que assistirá a esclarecer a tendência e selectividade baseada em sequência dos LTRs. No estudo de LTRs, é também relevante entender o impacto de satDNA a nível transcricional. Embora a família de HSat1A seja a menos abundante dos DNA satélites humanos, esforços iniciais demonstraram que estas sequências são activamente transcritas, enquanto também demonstram várias características que são consideradas interessantes para investigações adicionais relacionadas à actividade e função em regiões peri/centroméricas deste satDNA.

O objectivo principal deste trabalho foi realizar uma caracterização aprofundada de LTRs de mamíferos recorrendo a dados de sequenciação de genomas completos, com foco em dois organismos modelo: género *Peromyscus* e *Homo sapiens*. Isto implica identificar a abundância e diversidade de LTRs nos genomas, determinando as suas dimensões e número de cópias, caracterizando a suas variações em sequências e mapeando a sua localização cromossómica quando possível. Especificamente, este trabalho teve como objectivo avaliar LTRs específicos através de dados de sequenciação disponíveis de quatro espécies do género de *Peromyscus*, com intuito também de determinar as suas posições relativas numa comparação de cariótipo/ideograma entre as espécies. A medição do conteúdo GC, dimensões de monómeros e matrizes do PMSat também foi relevante para uma melhor descrição das matrizes de repetição deste satDNA dentro deste género. Também foi relevante para este trabalho a avaliação do impacto dos diferentes métodos de sequenciação na detecção e quantificação de LTRs. As LTRs têm-se demonstrado difíceis de detector e caracterizar devidamente devido às suas sequências contíguas altamente repetitivas. Com isso em mente, outro objectivo específico deste trabalho foi o aperfeiçoamento da caracterização da diversidade de matrizes repetitivas no genoma humano, tirando proveito de longas e contíguas leituras produzidas por tecnologia de sequenciação por nanoporos. Este estudo teve também como propósito a construção do cromossoma translocado Robertsoniano t(14;21) em células humanas, para uma melhor caracterização de LTRs envolvidos nesta translocação. Foi também importante para este trabalho a medição do número de cópias genómicas e da diversidade de produtos transcriptómicos do satélite humano HSat1A, com o intuito de revelar o panorama de transcrição deste satDNA.

A identificação de LTRs foi realizada com a ferramenta Tandem Repeat Finder, enquanto a caracterização foi desenvolvida com a ferramenta blastclust, um algoritmo de *clustering* baseado em sequência. Os métodos de sequenciação demonstraram algumas variações na detecção e quantificação de LTRs entre espécies. Todavia, ainda foi possível determinar que PMSat é o LTR mais abundante entre o género *Peromyscus*. O conteúdo GC dos monómeros de PMSat apresentaram uma variação entre 40-48% entre as quatro espécies seleccionadas. A dimensão dos monómeros de PMSat variam entre 340-345 bp entre as quatro espécies, enquanto a dimensão das matrizes demonstrou maior variação entre as espécies, no intervalo de 2,000-40,000 bp. Alguns LTRs foram identificados pela primeira vez, no entanto, apenas o LTR_PMAN_1 e o LTR_PMAN_2 apresentaram elevada abundância em comparação com outras novas classes identificadas. Localização relativa das matrizes de LTRs permitiram uma melhor visualização da interligação das classes de LTRs entre os cromossomas das espécies do género *Peromyscus*, permitindo também demonstrar a impulsão evolutiva dos LTRs, como a classe PMSat apresentando selectividade a nível cromossómico e de posição. Na detecção e quantificação de LTRs através de longas e contíguas leituras por nanoporos no genoma humano, dois conjuntos de dados de sequenciação do genoma humano foram usados, o NA12878 e o CHM13. Adicionalmente, foi usado neste estudo a linhagem celular GM03417, uma linhagem humana específica contendo uma translocação Robertsoniana t(14;21), para comparação com os resultados obtidos com esses conjuntos de dados de sequenciação. As quatro primeiras classes de satDNA agrupadas com mais matrizes foram as mesmas em todos os conjuntos de dados de sequenciação, com a ordem descendente ALR>BSR>HSat2>HSat1A. Para além disso, foi possível a identificação de seis novas classes de LTRs nos três conjuntos de dados de sequenciação, as quais estavam contidas nos primeiros 20 grupos de LTRs com mais matrizes. A técnica de *flow sorting* de cromossomas foi usada em conjunto com a sequenciação por nanopore para a construção do cromossoma translocado Robertsoniano t(14;21) em células humanas. No entanto, este método não produziu quantidade suficiente de dados para a sua análise. Para além disso, através dos dados obtidos foi possível verificar uma fragmentação de DNA significativa antes da preparação da biblioteca de sequenciação, o que poderá indicar que este método não seja o mais eficiente para o estudo de sequências repetitivas. Os dados de sequenciação de NA12878 foram usados para analisar o número de cópias genómicas de HSat1A, enquanto uma 5'/3' RACE (rápida amplificação de extremidades de cDNA) juntamente com sequenciação de elevado rendimento foi realizada para o estudo da diversidade dos produtos transcriptómicos também de HSat1A. As matrizes de HSat1A a nível genómico demonstram uma predominância para a dimensão de 42 bp, que é a sua forma de monómero único. No entanto, demonstra também uma predominância para uma organização de uma ordem superior (HOR) de repetições juntas em tandem (NTRs) 9-mer. Os produtos de 3' RACE demonstraram estar poliadenilados, indicando a ocorrência de transcrição, possivelmente pela RNA polimerase II. A montagem dos transcritos de HSat1A apresentou uma distribuição entre 51 e ~400 nucleótidos, demonstrando também picos correspondentes a múltiplos da dimensão do monómero de 42 bp. Elevada variabilidade de transcritos poliadenilados de HSat1A indica uma regulação complexa da poliadenilação alternativa deste satDNA.

Especificamente, no estudo de LTRs no género *Peromyscus* verificou-se padrões e relações que permitiram uma melhor caracterização de prévias e novas classes de LTRs identificadas. O posicionamento relativo da família satDNA mais abundante do género *Peromyscus*, PMSat, juntamente com outras classes de LTRs demonstraram uma preferência posicional e cromossómica destes elementos repetitivos. A tecnologia de sequenciação por nanoporos também demonstrou um grande potencial para a classificação e quantificação de LTRs no genoma humano. No entanto, alguns desafios na combinação desta tecnologia com *flow sorting* de cromossomas foram identificados na detecção e caracterização de LTRs. Algumas

novas classes de LTRs foram identificados no genoma humano. A caracterização da família de HSat1A revelou não só ser activamente transcrita, como também apresentar um elevado grau de variabilidade entre as sequências genómicas e trancriptómicas. Em geral, esta análise contribuiu para uma caracterização melhorada dos LTRs, com implicações na organização e evolução genómica. Contudo, investigação adicional e estudos funcionais são de devera importância para esclarecer funções e mecanismos específicos destes elementos repetitivos.

1. Introduction

This section provides an introductory summary of fundamental concepts regarding peri/centromeric regions and their components, as well as depicting general insights of nanopore sequencing technology and the objectives of this dissertation.

1.1 Centromere complexity and its multifaceted components

Centromeres play an important role in chromosome segregation of genetic material in both mitosis and meiosis. They represent the domain that defines the primary constriction of each eukaryotic metaphase chromosome. Other functions associated with centromeres are the recognition of homologous chromosomes during pairing in meiosis, attachment of sister chromatids before or until mitotic anaphase and during the first meiotic division, nucleation of the kinetochore apparatus, and cell cycle checkpoint control to regulate the metaphase-anaphase transition (Lee et al., 1997).

The peri/centromeric regions are composed of long tandem repeats (LTRs), mainly satellite DNA, which are highly repetitive sequences of DNA (Plohl et al., 2008). The satellite DNA sequences have been fundamental for the study of karyotypic evolution in eukaryotes (Adega et al., 2006; Gong et al., 2012; Kuhn et al., 2008; Langdon et al., 2000; Vondrak et al., 2020), understanding the foundation of abnormal centric fusion (Barra & Fachinetti, 2018; Lin & Davidson, 1974), defining the ancestry and evolution of satellite DNA families (Melters et al., 2013), and the distinction of homologous chromosomes (M. E. Aldrup-MacDonald et al., 2016). Other types of LTRs have also shown to be highly represented in centromeres, such as the case of some heterogeneous or transposable element (TE)-related superfamilies, however, these can be positioned anywhere on the genome (Komissarov et al., 2011; Sulovari et al., 2019). In some circumstances, noncoding LTRs have been associated with disease mechanisms (DeJesus-Hernandez et al., 2011), with evolutionary drive of speciation in eukaryotes (Raskina et al., 2008; Sulovari et al., 2019) and with transcriptomics implications on chromatin organization (Isiktas et al., 2022; Trigiante et al., 2021). Moreover, LTRs are also involved in structural chromosomal rearrangements, such as Robertsonian translocations (ROBs), which specifically involves the fusion of two acrocentric chromosomes at their centromeric regions, resulting in a single, larger chromosome (Poot & Hochstenbach, 2021). Even though some functions from these LTRs have been established, there are still unresolved cases due to constrictions regarding their highly repetitive contiguous sequences (Tørresen et al., 2019).

As stated before, satellite DNA is the main component of peri/centromeric regions and, subsequently, most of the focus will be on these sequences. This element is characterized by highly repeated segments of non-coding DNA (ncDNA) sequences, assembled into large tandem arrays of head-to-tail repeats in the constitutive heterochromatin, the eukaryotic chromosomal regions that stay condensed through the cell cycle (Plohl et al., 2008). The monomers of these sequences, which are the basic repeating units, are mainly composed of A+T and vary from a few base pairs (bp) to up more than 1 kilobases (kb) and can reach up to 100 Megabases (Mb) on array length (Plohl et al., 2008). The propensity of monomer satellite length seems to be around 150-180 bp and 300-360 bp, as it has been verified in satellites from both animals and plants. The explanation for this has been associated with the DNA length requirement of

wrapping of one or two nucleosomes (Henikoff et al., 2001). Contribution of satellite DNA to total genomic content has a significant impact on variability among species, as these sequences can sometime exceed 50% of total DNA. Consequently, eukaryotes acquire vast variation in genome size due to these sequences (Plohl et al., 2008). As a result of this great diversity of satellite DNA in sequence composition, genomic abundance, intricacy, and the existence of several families of satellite DNA that are unrelated, some potential functions from these sequences in the genome are still unknown. To this extent, though new data is still being acquired, connections between mechanisms and functions of theses satellite DNA are still very reliant on deduction rather than to experimental evidence (Plohl et al., 2008).

Human satellite DNA families comprise a wide range of sequence types and functions. The most abundant group is the centromeric alpha (α) satellite DNA family, influencing genome stability and recruitment of centromere and kinetochore proteins (McNulty & Sullivan, 2018). Other members are the beta (β) and gamma (γ) satellite DNA families, with the first family having shown to potentially originate from horizontal transfers in primates (Yang et al., 2020), while the latter being considered to control heterochromatin expansion in chromosomal arms (Lee et al., 1997). Additionally, human satellite DNAs HSat1 and HSat2/3 are also very important families represented in peri/centromeric regions (Prosser et al., 1986). HSat3 has shown to be located in the Robertsonian translocation (ROB) breakpoint of chromosomes 14 and 21 (Earle et al., 1992). Although HSat1 is the least abundant family of human satellite DNAs, early efforts demonstrate these sequences are transcriptionally active, while also showing several characteristics that are deemed to be interesting for further investigation regarding satellite DNA activity and function on peri/centromeric regions (Lopes et al., 2023). As aforementioned, satellite DNA transcription has been confirmed to have major implications on heterochromatin structure and centromeric protein recruitment, however, regarding this HSat1 family there are still many mechanisms and functions that are unknown, which is mainly due to their highly repetitive contiguous sequences.

Current strategies for LTR detection and characterization, mainly for satellite DNA, are based on genomic DNA digestion with restriction endonucleases, followed by sequence analysis of randomly cloned monomers or short multimers (Garrido-Ramos, 2017). However, new next-generation sequencing (NGS) technologies have been emerging, such as nanopore sequencing, which will assist in further elucidating the sequence-based arrangements and positioning of LTRs in chromosomes.

1.2 Advancing Long Tandem Repeat (LTR) analysis through Nanopore Sequencing Technology

Oxford Nanopore Technology (ONT) is an emerging sequencing method with promising potential to solve some of the current issues with assembly of large repetitive sequences, such as satellite DNA. This technology is based on sequencers using nanopore biosensors. In general, these biosensors can be classified into two main categories: solid-state nanopores that can be fabricated from several materials by usage of semiconductor production processes, that permit a wide variety of experimental conditions; and biological nanopores, consisting of genetically engineered transmembrane protein channels, that are embedded in a matrix. Currently, the biosensor used in ONT is a biological nanopore based on mutants of the Curlin sigma S-dependent growth (CsgG) nanopore from *Escherichia coli* (Magi et al., 2017; Y. Wang et al., 2021). CsgG is a secretion channel, implicated in curli formation. Curli are functional amyloid fibers that can be found

in the extracellular matrix of biofilms formed by some bacteria, such as α-*Proteobacteria* and γ-*Proteobacteria* (Goyal et al., 2014).

Library preparation strategies for nanopore sequencing can either be: 1D, where each strand is ligated with an adapter and pre-loaded motor proteins on both ends of the molecule, and sequenced independently; 2D, where the leader adapter guides fragments of double-stranded DNA (dsDNA) to the nanopore vicinity, and it starts the sequencing process by unzipping the dsDNA, enabling the template strand to pass through the nanopore, while at the end at the template strand, a hairpin adapter with pre-motor proteins is also sequenced with the complement strand; or $1D^2$, where each strand is ligated at both ends with a special adapter, increasing the probability that one strand will immediately be captured by the same nanopore following sequencing of the other strand of dsDNA (**Figure 1A**) (Goodwin et al., 2016; Magi et al., 2017; Y. Wang et al., 2021). Concomitantly, as the molecule of single-stranded DNA passes through the nanoscopic pore, a sensor measures ionic current shifts with a constant sampling frequency, with the additional shift between template and complement strand being recognized by the pore via the specific signal generated by an apurinic/apyrimidinic site located in the hairpin in the case of the 2D sequencing strategy (**Figure 1B**) (Magi et al., 2017). Data captured from raw current is then subjected to base calling with a machine learning approach (such as recurrent neural network, RNN, or hidden Markov Model) (**Figure 1C**) to obtain a consensus sequence for the template only (1D) or both template and complement strands separately (2D) (**Figure 1D**) (Magi et al., 2017). 2D and $1D^2$ sequencing strategies have an increased accuracy detection compared to 1D sequencing strategy, however, with the improvement of new base-calling algorithms, 1D read accuracy has also improved (Y. Wang et al., 2021).

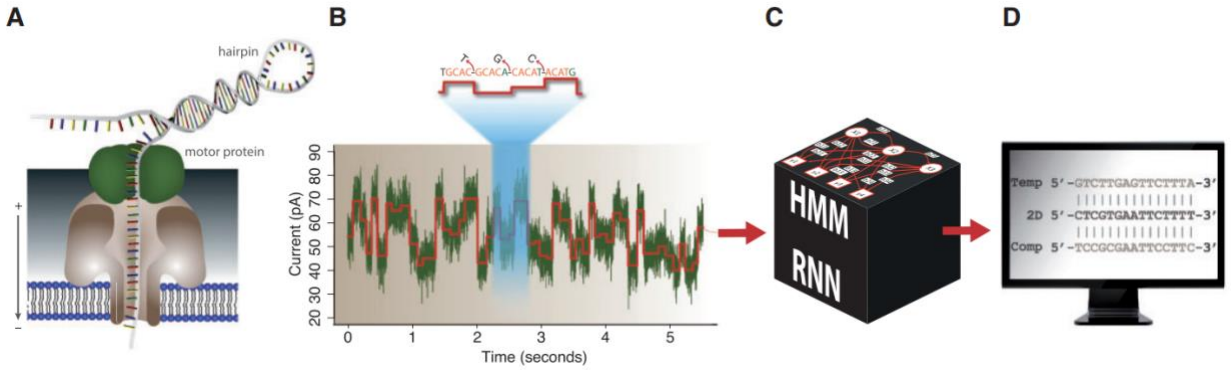

Figure 1 – The Oxford Nanopore sequencing process and performance. The motor protein unwinds the dsDNA allowing ssDNA to pass through the pore, while a sensor measures ionic current shifts (**A**) with a constant sampling frequency (at present 5000 Hz). Raw ionic current signals are segmented into discrete 'events' summarized by mean, SD and length (**B**). Segmented events are then analyzed with machine learning approach (black box, **C**) that outputs the sequence of template and complement signals (**D**) (Magi et al., 2017).

Application of these library preparation strategies using nanopore sequencing technology have been used in emerging projects, such as the Telomere-2-Telomere (T2T) consortium, which has solved major gaps in the human genome is the (Nurk et al., 2022). Their efforts have managed to correctly identify and quantify the sequences in the major peri/centromeric gaps of the human genome, while further driving the study of these regions (Altemose, 2022; Logsdon & Eichler, 2023; Lopes et al., 2023).

1.3 Satellite DNA: Exploring its role in centromere structure, chromosomal rearrangements, and evolution

The structure of the centromere is complex and involves a variety of molecular components, with satellite DNA playing a prominent role in defining its structure and function (Malik & Henikoff, 2009). Satellite DNA is involved in the formation of kinetochores, which are essential for the proper segregation of chromosomes during cell division (Shatskikh et al., 2020). It also has been associated with regulatory intron-mediated mechanisms that are important for gene expression (Fingerhut & Yamashita, 2022), and determines chromatin organization (Brändle et al., 2022; Thakur et al., 2021). Furthermore, satellite DNA strongly influences equilocality of centromeres in chromosomes, which refers to the tendency of centromeres to occupy fixed positions relative to other genetic elements on chromosomes (John et al., 1985; Ruiz-Ruano et al., 2016) and is thought to play a role in the evolution of karyotypes in eukaryotes (Adega et al., 2009; Smalec et al., 2019; K. Wang et al., 2022; Zattera et al., 2020). These sequences also play a crucial role in maintaining the structural and functional integrity of chromosomes (Plohl et al., 2008). The movement of a chromosomal locus as a result of rearrangements into the satellite DNA region can lead to a change in the activity of genes located in that locus because of the "position effect" (Zhimulev & Belyaeva, 2003). Moreover, rearrangement of satellite DNA can lead to genome instability, which can result in altered gene expression patterns, due to changes in the position of genes relative to regulatory elements (Fournier et al., 2010). The repetitive nature of the satellite DNA sequences makes it susceptible to recombination during cell division, which can lead to structural abnormalities in chromosomes (Giunta & Funabiki, 2017). Rearrangement of these sequences may also confer susceptibility to ROBs, which could lead to chromosomal disorders such as Down syndrome (Bandyopadhyay et al., 2001), although the mechanisms for this are still unknown. Additionally, satellite DNA structures can suffer rearrangements due to transposable elements (TEs) and other repetitive sequences being inserted into adjacent regions (Klein & O'Neill, 2018). Moreover, due to their tandemly repetitive nature, satellite DNA can undergo rapid evolution and contribute to chromosomal rearrangements, with the occurrence of events such as translocations and inversions (Louzada et al., 2020). Concerning specifically ROBs, these are a common type of chromosomal rearrangement that occurs between acrocentric chromosomes that involve the fusion of two chromosomes at their centromeric regions, resulting in a single, larger chromosome. Satellite DNA is often found at the breakpoints of these translocations, which could be an indicator of a crucial role of these sequences regarding these events (Altemose et al., 2014; Puppo et al., 2020).

Chromosome rearrangements in peri/centromeric regions may drive speciation events by contributing to reproductive isolation, but the relationship between the evolution of heterochromatic sequences and the karyotypic dynamics of these regions is poorly understood. In the order Rodentia of the genus *Peromyscus*, a single conserved satellite DNA sequence (PMSat) is located in recurrent sites of chromosome rearrangements and heterochromatic amplifications (Louzada et al., 2015). Despite wide variation in the copy number and location of repeat blocks among different species, PMSat maintains a conserved sequence and homogenized tandem repeat structure, defying predictions of molecular drive (Smalec et al., 2019). The conservation of this satellite monomer results in common, abundant, and large blocks of chromatin that are homologous among chromosomes within one species and among diverged species. The study of other LTRs in these species and including PMSat, can provide insights into molecular drives behind their wide range of ecological adaptations and on chromosomal evolution.

1.4 Strategies for tackling repetitive sequences in genome assembly

Repetitive sequences have always represented a great challenge for correct assembly and copy number assessment, especially in LTRs, which can reach massive array lengths (Plohl et al., 2008). In accordance with this, several methodologies have been fundamental for tandem repeat analysis. The most common tool employed for this analysis is the Tandem Repeats Finder (TRF) (Benson, 1999). This tool allows for the detection, quantification and establishing monomer consensus of tandem repeats located in provided DNA sequences. Additionally, RepeatMasker (developed by A.F.A. Smit, R. Hubley, and P. Green; see http://www.repeatmasker.org/) was also designed with the intent to identify and annotate repetitive elements in DNA sequences, and similarly contributed immensely for tandem repeat analysis. Nevertheless, research studies to detect and classify these tandem repeats are highly dependent on specific parameters, such as selecting for minimum monomer length and non-overlapping LTRs, in order to retrieve the most probable LTR correspondent to its detected location (Easterling et al., 2020; Ummat & Bashir, 2014).

Some concepts are of great importance to understand the process of LTR detection and characterization. As mentioned before, sequencing is the first step of the analysis, which produces reads. The reads are the primary unit of sequencing, as they constitute the raw sequences retrieved from the organism DNA. To improve the study of DNA sequences, reads are then assembled at high confidence into a contiguous fragment, the contig. Assembly of contigs is performed by overlapping these reads obtained from sequencing and then merging them together to retrieve an elongated and/or a more accurate consensus sequence. When forming these contigs, there are several regions that may contain highly repetitive or difficult sections between them. As such, when linking several contigs together these then contain gaps between them. These linked contigs are known as scaffold. There are some methods that provide enough evidence to support that a set of contigs are positioned at a certain distance from each other, such as paired-end or mate-pair reads that bridge two contigs (McCartney et al., 2019). Reads obtained from sequencing allow assessment of the sequencing coverage of the technology used. Sequencing coverage was described as LN/G, where L is the average read length, N is the number of reads, and G is the haploid genome length (e.g., an average read length of 6,200 bp, from $3x10^7$ reads for the human genome of 3.1Gb would give an estimated coverage of 60x) (Sims et al., 2014). This sequencing coverage is assessed for each genome assembly. A genome assembly is the reconstruction of a complete or near-complete representation of the genome of an organism using DNA sequencing data. It involves piecing together shorter DNA fragments (reads) obtained through sequencing into longer contiguous sequences (contigs/scaffolds) or complete chromosomes. An assembly can be composed of only contigs, only unplaced scaffolds, only chromosomes, or a combination of the three (Baker, 2012).

Even though downstream computational analysis has shown great improvement, there are still some challenges to consider. The study of translocated chromosomes focusing on repetitive sequences cannot be performed in an efficient manner through whole genome sequencing approaches, as this would require the generation of a huge amount of data that is irrelevant for the question to be addressed to ensure appropriate coverage of the target region. Therefore, other methods need to be deployed in order to facilitate sufficient sequencing data collection for specific translocated chromosomes. A relevant approach in this context is the flow-sorting technique, that can be used to isolate specific chromosomes from a population of cells, and then subject them to sequencing (Doležel et al., 2021; Kuderna et al., 2019). By separating individual chromosomes, flow-sorting can greatly reduce the complexity of the DNA sample and increase the

sequencing coverage of the target chromosome. The process of flow-sorting involves labeling chromosomes with fluorescent dyes and passing them through a flow cytometer, which sorts the chromosomes based on their scatter properties and fluorescence intensity. Overall, flow-sorting offers a valuable tool to study specific chromosomes, including those involved in translocations.

1.5 Objectives

The main objective of this work was to perform an in-depth characterization of mammalian LTRs resorting to whole genome sequencing data, with focus on two model organisms: *Peromyscus* genus and *Homo sapiens*. This involves identifying the abundance and diversity of LTRs within the genome, determining their length and number of copies, characterizing the variation in their nucleotide sequence, and mapping their chromosomal location when possible.

Specifically, the study of the LTR class diversity present in *Peromyscus* genus genomes was of interest, centering on the satellite PMSat family, in an effort to evaluate their species-specific LTRs, while also determining their relative position between the species for karyotype/ideogram comparison. Assessment of the impact from distinct sequencing methods in LTR detection and quantification was an additional aim regarding this specific analysis.

Additionally, another aim of this work was to improve the characterization of the diversity of repetitive arrays in the human genome, taking advantage of long contiguous reads produced by nanopore sequencing technology. Furthermore, this study aims to re-construct the Robertsonian translocation region in chromosome t(14;21) in human cells, for a better characterization of the long tandem repeats involved in this translocation. It was a final aim of this work to characterize human satellite HSat1A genomic copy number, sequence variation, and transcription product diversity with the purpose of unraveling the transcriptional landscape of this human satellite.

2. Methods

2.1 Whole genome datasets

The genomes selected for the LTR family diversity study on the *Peromyscus* genus were from the *Peromyscus maniculatus* (PMAN 1.0, PMAN 2.1 CHR and PMAN 2.1 CONTIGS), the *Peromyscus californicus* (PCAL), the *Peromyscus eremicus* (PERE) and the *Peromyscus leucopus* (PLEU) species. These genomes are reported in GenBank under accession numbers GCA_003704035.1 (PMAN 1.0), GCA_003704035.3 (PMAN 2.1 CHR), RCWR01000001-RCWR01155965 (PMAN 2.1 CONTIGS), GCA_007827085.3 (PCAL), GCA_902702925.1 (PERE) and GCA_004664715.2 (PLEU). For the study of LTRs on long contiguous reads from nanopore sequencing in human genome two Whole Human Genome Sequencing Projects were selected, the NA12878 (https://github.com/nanopore-wgs-consortium/NA12878) and CHM13 (https://github.com/marbl/CHM13). The header of each read was renamed by numerical order. The length and abundance of raw reads from each assembly or dataset was determined for the whole dataset and different sequence categories with the use of custom in-house R (R version 4.2.2) scripts (https://github.com/GamaPintoLab/DanielEleuterio-MSc-Thesis).

2.2 Cell culture, genomic DNA isolation and Oxford Nanopore Technology (ONT) sequencing

In this work the human fibroblast GM03417 cell line (Coriell Institute) was used, which presents mosaicism with 32% of cells being a balanced 45,XX, t(14;21) (ISCN: 46,XX,der(14;21)(14qter> 14q10::21q10>21qter),+21[34]/45,XX,der(14;21)(14qter>14q10::21q10>21qter)[16]). The GM03417 cell line was grown according to the protocol from Coriell Institute. $2x10^7$ freshly cultured fibroblasts from the GM03417 cell line were used to extract genomic DNA with the Qiagen Genomic Tips 100/G extraction kit, described to yield high quality purified DNA-fragments in the range between 20-150kb (Jain et al., 2018). Using this method, it was possible to isolate ~100µg of high-quality DNA (as quantified by Qbit). Genomic DNA from the GM03417 cell line was prepared for ligation genomic DNA 1D R9.4 chemistry sequencing and subjected to one round of library preparation using the SQK-LSK109 Kit from ONT. This was followed by two runs of nanopore sequencing on a FLO-MIN106 cell, performed on a GridION sequencer. Basecalling was performed with Guppy, which is only available via their community site (https://community.nanoporetech.com) and the results were compiled into FASTQ format. These FASTQ files were then converted into FASTA format for analysis. The sample with the flow sorted chromosomes from the GM03417 cell line was prepared for ligation genomic DNA 1D R9.4 chemistry sequencing in-house and subjected to one round of library preparation using the SQK-LSK109 Kit from ONT. This was followed by one run of nanopore sequencing on a FLO-MIN106 cell, performed on a GridION sequencer. Basecalling was performed with Guppy, which is only available via their community site (https://community.nanoporetech.com) and the results were compiled into FASTQ format. These FASTQ files were then converted into FASTA format for analysis. The sequencing was stopped at an early stage

due to a low sequencing data yield. To optimize the reading experience of this work, the sequencing data obtained from the GM03417 cell line will be referred to as the GM03417 dataset.

Samples were generated by the host lab and libraries were synthesized and sequenced at the BioISI Genomics facility.

2.3 Flow-sorting of chromosomes in GM03417 cell line

Purification of flow-sorted chromosomes was performed by the CytoGenomics Lab (UTAD), following Kuderna et al. 2019 protocol with modifications: the sorted chromosomes were treated overnight with 10µl of proteinase K (20mg/ml) at 50ºC; after treatment the solution was transferred to a Pur-A-Lyzer Maxi Dialysis column (Sigma) for dialysis against 500ml 1xTE buffer, in order to remove the proteinase K as well as chromamycin-A3 and Hoeschst 33258 (intercalating dyes used for the chromosome flow-sorting); dialysis was carried for 48h exchanging the buffer every 10-16h; after the dialysis the DNA was transferred to a 1.5 ml tube and quantified with Qubit using dsDNA HS Kit, with a Qubit reading of 59ng/ml and total sample volume of ~500µl. This sample contained 330,000 chromosomes isolated and was stored at 4ºC.

Raw reads from sequencing performed on the flow-sorted chromosomes were aligned using the minimap2 tool (Li, 2018) (https://github.com/lh3/minimap2) to the 24 chromosomes of the human genome assembly GRCh38.p13, individually. From this alignment, quantification of mapped reads was performed.

2.4 LTR detection and clustering analysis

The detection of tandem repeats was performed using the Tandem Repeat Finder (TRF) algorithm (Benson, 1999), with the following parameters: *match*, *mismatch* and *delta* were set to 2, 5, 7, respectively; *match_probability* was set to 80; *indel_probability* was set to 10; the *MinScore* (minimum alignment score to report) was set to 50 and *MaxPeriod* (maximum period size to report) was set to 2000. TRF output analysis was performed with custom in house scripts in R (R version 4.2.2) (https://github.com/GamaPintoLab/DanielEleuterio-MSc-Thesis). Redundant entries from the TRF output were eliminated, considering all embedded LTR arrays and for those that possessed the same sequence coordinates, the LTR with the larger consensus length was discarded.

A clustering algorithm, blastclust (Altschul et al., 1990) was considered LTR characterization. This was used for the clustering of sequence-based similarity within LTRs detected assembly and dataset. This clustering analysis was performed with parameters of a minimum length coverage of 51% and a similarity threshold of 50%. Based on this, LTRs within these thresholds were clustered to the same group.

Quantification of alignments of satDNA arrays (ALR, BSR, HSat1A and HSat2) from GM03417, NA12878 and CHM13 with chromosomes 14, 21, and both together from the human genome assembly GRCh38.p13, was performed using the BLAST tool (Z. Zhang et al., 2000).

2.5 Annotation and classification of LTR classes

The monomer sequences corresponding to each group that were clustered together were then compared to a repetitive sequence database Dfam (https://dfam.org/home) (Hubley et al., 2016), and assigned their name matching with those repetitive elements in the database. The LTR groups from the *Peromyscus* genus analysis that had not been identified in Dfam had their names assigned according to their assembly, numbered from largest to smallest group (e.g., PMAN: LTR_PMAN_1 to LTR_PMAN_11). For the nanopore sequencing datasets from the human genome, a similar process was performed for LTR groups that had not been identified in Dfam, with their names also numbered from largest to smallest group (e.g., H_LTR_1 to H_LTR_6). The BLAST tool (Z. Zhang et al., 2000) was used to identify similar LTR groups across assemblies in the *Peromyscus* genus LTR analysis, considering the first species in which the LTRs were originally identified, following the order PMAN>PCAL>PERE>PLEU. This process was also performed on the nanopore sequencing datasets from the human genome; however, these maintained a unique identification letter representative of human (H) and numbered following the order GM03417>NA12878>CHM13. Groups that contained a query cover >80% and identity score >80% in other assemblies were aggregated into a class. Clusters with values below the cut-offs maintained their primary classification. A representative workflow of this process can be found in **Figure 3A**.

Comparative analysis based on GC-content, monomer and array length was performed on PMSat arrays detected in the *Peromyscus* genus assemblies selected, using custom scripts in R (R version 4.2.2) (https://github.com/GamaPintoLab/DanielEleuterio-MSc-Thesis).

2.6 Distribution and statistical analysis of PMSat characteristics across the *Peromyscus* genus

Selection of PMSat arrays for a distribution and statistical test analysis across the *Peromyscus* genus assemblies was performed. The ANOVA One-way statistical test was selected for this analysis, with the additional use of a Tukey Post-Hoc test for a pairwise comparison of PMSat monomer length, monomer GC-content, array length, and array GC-content among the *Peromyscus* genomes. The analysis was performed using custom scripts in R (R version 4.2.2) (https://github.com/GamaPintoLab/DanielEleuterio-MSc-Thesis).

2.7 Relative positioning and orientation of LTR arrays

Selection of LTR arrays for relative positioning and orientation on chromosomes from PMAN, PCAL, PERE and PLEU assemblies was based on their presence in at least two species, such as described in **Figure 3**. The output information from the TRF analysis performed on these four *Peromyscus* spp. provided the coordinates of the LTR arrays on the chromosomes, which was used for relative positioning on each chromosome correspondent with each species. Additionally, orientation of each LTR array was

defined based on a randomly selected monomer corresponding to each LTR class, for a baseline comparison between LTR arrays on each species.

2.8 Quantification and periodicity study of HSat1A

The HSat1A repetitive sequence was extracted from the Dfam database (https://dfam.org/), with the name SAR, accession DF0001062.4. Quantification was performed using RepeatMasker (Smit et al., 2013) to detect the presence of HSat1A (SAR) on reads from NA12878 sequencing data. For the periodicity studies of HSat1A repetitive sequences, reads with a number higher than 400 Kbp containing only these sequences were selected. Then, the NTRprism (https://github.com/-altemose/NTRprism) scripts were used on the selected reads.

2.9 3' RACE, RACE-seq, and sequencing analysis

HeLa cDNA was prepared using the 5′/3′ RACE (rapid amplification of cDNA ends) Kit, 2nd Generation (Roche), and subjected to PCR using the provided PCR anchor primer (5'-GACCACGCGTATCGATGTCGAC-3') and the HSat1A forward primer (5'-TGTGCGGTACATAAGATATCAAAG-3') at the CytoGenomics Lab (UTAD). 3′ RACE was coupled with high-throughput sequencing, performed by STAB VIDA NGS sequencing service. The analysis of the generated sequence raw data was carried out using CLC Genomics Workbench 12.0.3 (https://www.qiagenbioinfor-matics.com/). The following data processing is detailed in **Figure 10**. RACE-PCR was followed by paired-end 300-nt Illumina sequencing. To evaluate the quality of the reads throughout the workflow, FASTQC (Andrews, 2010) was used. CutAdapt (Martin, 2011) was used to remove the Universal Adaptors on the extremities of the reads. The paired reads were merged using the PEAR (J. Zhang et al., 2014) tool. To guarantee the quality of the reads, a score Phred of equal or higher than 30 was applied with the tool Seqkit (Shen et al., 2016). Furthermore, to also guarantee that at least one monomer of HSat1A was present on every read, selection for the size of the sequences to be at least 85 bp or higher was applied, considering the downstream removal of the Oligo Anchor primer of the reads. For the next step, all the reads were set in the same orientation, to ensure that we could proceed with a Multiple Sequence Alignment analysis downstream. This was also done with the tool Seqkit (Shen et al., 2016) and the GNU grep. Then, the identification of reads containing the HSat1A (SAR) satellite sequence was performed with RepeatMasker (Smit et al., 2013). The count and removal of duplicates within these reads containing the HSat1A (SAR) satellite sequence were performed using the Seqkit (Shen et al., 2016) tool. Subsequently, clustering of these sequences was achieved with the MESHClust v3.0 program (Girgis, 2022), selecting for a threshold identity score of 90% to determine the cluster membership. Multiple sequence alignment was performed with an R (R version 4.2.2) script on cluster center sequences to produce a dendrogram. From the clustering, it was possible to discover motifs based on the sequence in each group using the Improbizer tool (Ao et al., 2004). The scripts and produced data are publicly available at https://github.com/GamaPintoLab/HSAT1A-transcript-analysis.

3. Results

3.1 Study of LTR diversity in *Peromyscus* spp. genome assemblies

This section describes the results obtained in the frame of the first objective of this thesis, to characterize LTR diversity in the *Peromyscus* genus. The interest in this topic stemmed from the previous identification in *Peromyscus eremicus* of the PMSat LTR by the CytoGenomics Lab (UTAD) (Louzada et al., 2015), leading to the exploration of tandem repeats within selected *Peromyscus* genus available genome assemblies, to further improve our understanding of the complexity of these sequences within these genomes.

3.1.1 Overview of publicly available *Peromyscus* genomes datasets

The study began with a survey of genomes of the *Peromyscus* genus in public repositories. *Peromyscus maniculatus* version 1.0 (PMAN 1.0), the contigs of *Peromyscus maniculatus* version 2.1 (PMAN 2.1 CONTIGS) and the chromosomes with unplaced scaffolds of the same species (PMAN 2.1 CHR), the *Peromyscus californicus* (PCAL), the *Peromyscus eremicus* (PERE) and the *Peromyscus leucopus* (PLEU) species, were identified and downloaded for analysis (**Table 1)**. The *Peromyscus maniculatus* genome had two assemblies available (PMAN 1.0 and PMAN 2.1), increasing the information available to study repetitive sequences. For a better comparison in terms of similar contig/scaffold length between PMAN 1.0 and PMAN 2.1, contigs from the PMAN 2.1 (PMAN 2.1 CONTIGS) assembly were also selected for this analysis. The PMAN 1.0 and PMAN 2.1 CONTIGS assemblies do not possess assembled chromosomes. All other genome data only had one assembly available.

Firstly, through the retrieval of length differences and assembly methods used, dataset discrepancies were analyzed for any implication in the subsequent LTR analysis. Sequencing data from all assemblies was collected and metrics based on unplaced scaffold length were calculated for this purpose (**Table 1**). The number of contigs from the PMAN 2.1 CONTIGS assembly is much higher than the total number of scaffolds and contigs from the PMAN 1.0 assembly. Moreover, both of these assemblies have a minimum scaffold or contig length of 201 bp, although the contigs from the PMAN 2.1 CONTIGS assembly have a much lower average and maximum length than the scaffolds and contigs from the PMAN 1.0 assembly. The unplaced scaffolds from the PMAN 2.1 CHR assembly had similar average length with the contigs from the PMAN 2.1 CONTIGS assembly. Additionally, the maximum length was considerably higher in the unplaced scaffolds from the PMAN 2.1 CHR assembly, however, still much lower than that of the PMAN 1.0 assembly. These differences between the reconstructed sequences of the three PMAN assemblies suggest there is some length distribution variability in each one that needs to be assessed before the LTR analysis. Moreover, it will be important to assess that variability across the assemblies from other *Peromyscus* genomes.

Table 1 – Overview of publicly available *Peromyscus* genus genomes datasets, sequencing, and assembly methods. Quantification and distribution of contigs/scaffolds belonging to each assembly. *The nucleotide sum value is equal to the genome size because these assemblies do not have their sequences assembled into chromosomes. **The custom method is referenced in (Long et al., 2019).

For a better representation of the differences between the assemblies from the *Peromyscus* genomes, a distribution of unplaced scaffold/contig length for all assemblies was generated (**Figure 2**).

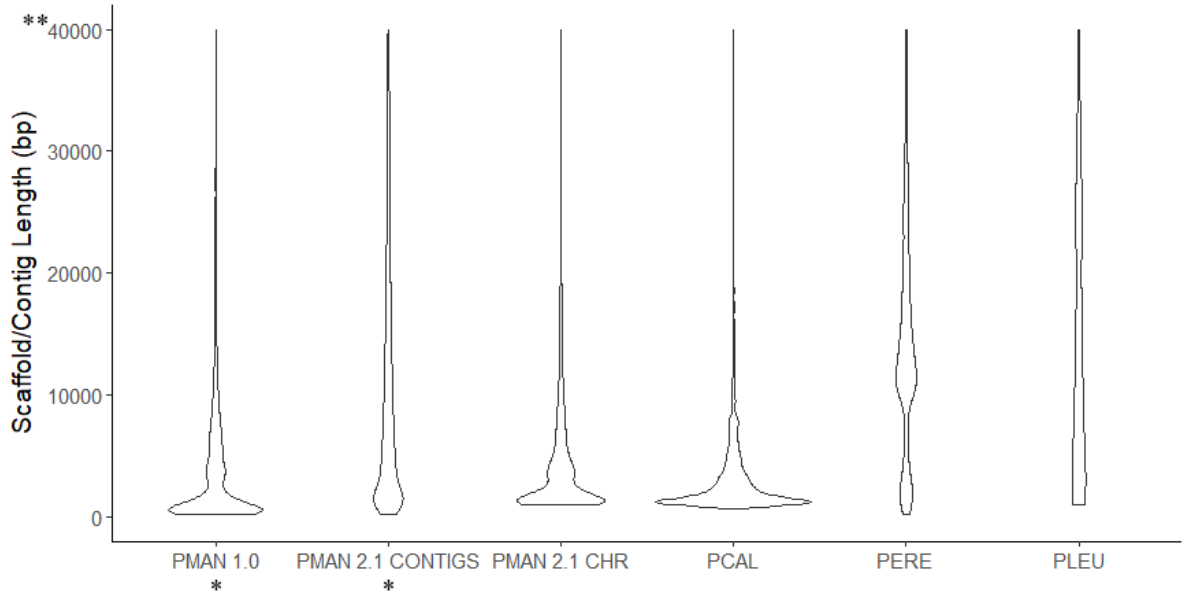

Figure 2 – Comparison of unplaced scaffolds length variation of all assemblies. A violin plot for length distribution of contig/scaffolds, or unplaced scaffolds in each assembly. The range length was restricted between 0 and 40,000 bp. *PMAN 1.0 and PMAN 2.1 CONTIGS contain all scaffolds/contigs from their assemblies, while the length variation of other assemblies only represents unplaced scaffolds. **The maximum length presented was selected based on the third quartile length (bp) (Q3) and for better visualization of the distribution.

The length distribution between the scaffolds from the PMAN 1.0 assembly and the unplaced scaffolds from the PMAN 2.1 CHR assembly could indicate similar sequencing data for repetitive elements analysis, as both revealed a similar length distribution (**Figure 2**). Nevertheless, the scaffolds and contigs from the PMAN 1.0 assembly and the contigs from the PMAN 2.1 CONTIGS assembly have similar nucleotide sum (bp) and also a higher number in comparison with the PMAN 2.1 CHR assembly, which might provide a more representative landscape of the LTRs present in the genome of this species (**Table 1**).

The PCAL assembly appears to have a similar sequencing data length distribution of unplaced scaffolds relative to that of the PMAN 1.0 and the PMAN 2.1 CHR assemblies, although the unplaced scaffolds nucleotide sum is double that of the PMAN 2.1 CHR assembly (**Figure 2**; **Table 1**). Moreover, the distribution of unplaced scaffolds in the PCAL assembly shows a higher quantity of shorter length sequences in comparison to the PMAN 1.0 and the PMAN 2.1 CHR assemblies (**Figure 2**).

The PERE assembly has a lower number of unplaced scaffolds when compared to the PMAN 2.1 CHR assembly (**Table 1**). The unplaced scaffold nucleotide sum is also double that of the PMAN 2.1 CHR assembly. However, the length distribution of the unplaced scaffolds for the PERE assembly is concentrated at a higher length, with an average of ~12,000 bp (**Figure 2**).

The unplaced scaffolds from the PLEU assembly have a length distribution more similar to those from the PERE assembly (**Table 1**; **Figure 2**). Moreover, the unplaced scaffold nucleotide sum is similar to that of the PMAN 2.1 CHR assembly (**Table 1**). This might have implications in the quantification of LTRs.

Based on this analysis, it can be concluded that the publicly available genome assemblies for the *Peromyscus* genus can support the comparative analysis of LTR sequences present in different species, although with some limitations.

3.1.2 Exploring LTR array detection and PMSat satellite distribution in *Peromyscus* genomes

In this section, detection of LTR arrays was performed in the selected genomes of PMAN (PMAN 1.0; PMAN 2.1 CONTIGS; PMAN 2.1 CHR), PCAL, PERE and PLEU. Initially, quantification of LTR arrays and nucleotide sum were evaluated to assess LTR characteristics across the *Peromyscus* genus. Subsequently, a clustering algorithm was used to discriminate specific LTR classes. From this, in agreement with previous data (Louzada et al., 2015; Smalec et al., 2019), a predominant LTR class was evident on first examination, the PMSat satellite family. Considering this, PMSat was also selected for quantification of its arrays and nucleotide sum evaluation, with the aim of comparing these values with the overall LTR population (**Table 2)**.

The first assembly, PMAN 1.0, showed to have the highest number of LTR arrays detected of all PMAN assemblies, in addition to the highest array nucleotide sum. However, regarding the PMSat arrays, there are some slight variations in comparison with the overall LTR detection. The PMAN 1.0 assembly also had the highest number of PMSat arrays detected and subsequent nucleotide sum, however, their relative ratio to the number of LTR arrays and LTR nucleotide sum (52.03% and 62.37%, respectively) is much lower in comparison to the other assemblies of PMAN 2.1 CHR (70.86% and 78.26%, respectively) and of PMAN 2.1 CONTIGS (89.92% and 91.55%, respectively) (**Table 2**).

The vast number of contigs contained in the PMAN 2.1 CONTIGS genome does not seem to improve LTR array detection, with 784 arrays being detected, against the 1672 arrays in the PMAN 1.0 assembly, which had a much lower number of scaffolds in its assembly (**Table 1-2**). The discrepancy in scaffold and contig length distribution between the PMAN 1.0 assembly and the PMAN 2.1 CONTIGS assembly could account for this difference, as the former exhibits smaller scaffolds compared to the distribution of contigs in the latter (**Figure 2)**. Moreover, despite the PMAN 2.1 CONTIGS assembly having a lower count of detected LTR arrays compared to the PMAN 1.0 assembly, this does not seem to be connected with the number of contigs or the overall higher median length value in the PMAN 2.1 CONTIGS assembly (**Table 1-2**). However, it is possible that the presence of a substantial number of long scaffolds in the PMAN 1.0 assembly could have influenced the detection of LTR arrays. This might explain the observed half-term value of 937 LTR arrays detected in the PMAN 2.1 CHR assembly (**Table 1-2**).

To further explore this topic, the percentage of LTR and PMSat arrays detected in the chromosomes and unplaced scaffolds was assessed (**Table 3**). The ratio of PMSat/LTR arrays in the chromosomes of PMAN 2.1 CHR and the scaffolds of PMAN 1.0 exhibits a notable similarity. Additionally, the ratio of PMSat/LTR arrays in unplaced scaffolds in the PMAN 2.1 CHR assembly is similar to the ratio found in

Table 2 – Overview of LTR and PMSat detection in assemblies from *Peromyscus* genus genomes. Quantification of LTR and PMSat arrays, and nucleotide sum was performed, with calculation of their relative ratios, and with the genome size.

	Genome Assemblies

% (PMSat/LTR arrays) in unplaced scaffolds	52.03%	89.92%	88.31%	36.49%	58.20%	53.09%

contigs from the PMAN 2.1 CONTIGS assembly. As these scaffolds were not placed in any region of the chromosomes, this might suggest that PMSat arrays detected in unplaced scaffolds from the PMAN 2.1 CHR assembly mainly derive from the PMAN 2.1 CONTIGS PMSat arrays that overlapped in the assembly process. The number of LTR arrays in the PMAN 2.1 CHR assembly showed a similar distribution between the chromosomes and unplaced scaffolds. However, for the detected PMSat arrays, the distribution appears slightly different, favoring the unplaced scaffolds in comparison to the chromosomes.

The other *Peromyscus* genomes (PCAL, PERE and PLEU) also have many variations between the number and cumulative length of detected arrays. The PCAL assembly showed a slightly higher number of LTR arrays detected in comparison with the PMAN 2.1 CHR assembly (**Table 2)**, although the observed length distribution of their respective reconstructed sequences is similar in both (**Figure 2**), which might be due to the maximum unplaced scaffold length from the PCAL assembly being much larger (**Table 1**). Moreover, the PCAL assembly has a slightly lower number of PMSat arrays detected in comparison with the PMAN 2.1 CHR assembly (**Table 2)**, which might be due to it having a higher percentage of LTR arrays detected in unplaced scaffolds (**Table 3**), considering these reconstructed sequences have a higher distribution of shorter lengths (**Figure 2**). Additionally, this may mean that the PCAL assembly has more of other (non-PMSat) LTR arrays.

The PERE genome appears to have the highest number of detected LTR arrays and corresponding nucleotide sum of all *Peromyscus* genomes in this study (**Table 2**). Even so, considering the PERE assembly has a lower number of unplaced scaffolds than the PMAN 2.1 CHR and PCAL assemblies (**Table 1**), this large number of LTR arrays detected could be due to the length of the unplaced scaffolds of the PERE assembly being at least two to three times larger than the length of unplaced scaffolds of PMAN 2.1 CHR and PCAL (**Figure 2**). The analysis also showed that the LTR arrays from the PERE assembly are mostly detected in chromosomes (**Table 3**). Concerning the PMSat arrays detected in the PERE assembly, it is possible to distinguish that there is a partial increase of PMSat arrays and subsequent nucleotide sum, however, their ratio in relation to the LTRs are the lowest of all the assemblies (**Table 2**). Moreover, most of the PMSat arrays in this genome are found in the unplaced scaffolds, while the PMSat arrays detected in the chromosomes only account for 7.69% (**Table 3**).

The PLEU assembly has the less LTR arrays and LTR nucleotide sum in comparison to all other assemblies (**Table 2**), which could be associated with having the lowest number of unplaced scaffolds across all *Peromyscus* genomes. The length distribution of the unplaced scaffolds from the PLEU assembly are more similar to that of the PERE assembly (**Figure 2**), also corresponding to the pattern observed of LTR arrays detected in chromosomes in comparison to unplaced scaffolds (**Table 3**). However, the ratio of PMSat/LTR arrays detected in chromosomes is not as low as in the PERE assembly, while the ratio of PMSat/LTR arrays in unplaced scaffolds is also similar to that of the PERE assembly (**Table 3**). The impact on overall LTR detection in the PLEU assembly in comparison to the other assemblies may be due to the custom method used for assembly of the reconstructed sequences.

It was possible to conclude that PMSat detection was in similar proportion across all the genomes, even with some variations regarding LTR detection, namely in the PERE and PLEU assemblies.

3.1.3 Clustering analysis of LTR arrays from *Peromyscus* genomes

To assess the similarities between LTR arrays detected within each assembly, a clustering analysis was performed to identify LTR groups (**Table 4**; see also **Supplementary Table 1-6**). LTR groups that were not described in Dfam (Storer et al., 2021), were named according to their assembly, numbered from largest to smallest (Ex: LTR_PMAN_1 to LTR_PMAN_11). The BLAST tool (Z. Zhang et al., 2000) was used to identify similar LTR groups across assemblies, considering the first species in which the LTRs were originally identified, following the order PMAN>PCAL> PERE>PLEU. Groups containing a query cover >50% and identity score >50% in other assemblies were aggregated into a class, while those within the same class that had a query cover >80%, and identity

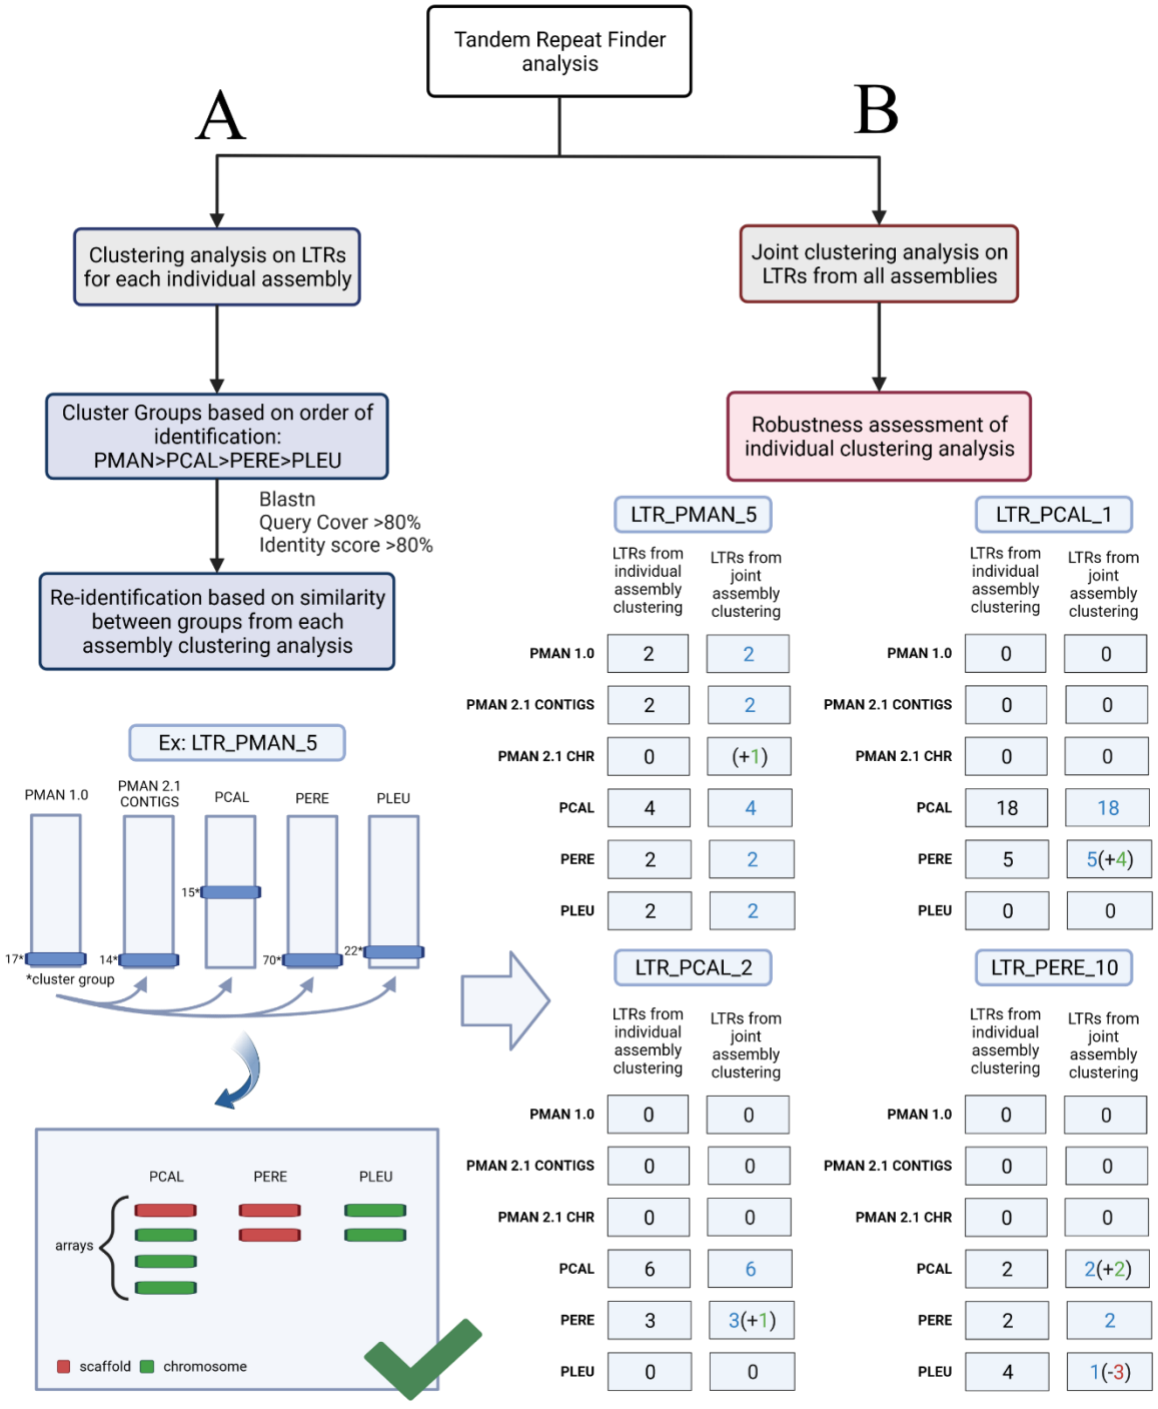

Figure 3 – Overview of the LTR clustering workflow. A: Assembly-centered LTR group identification. Clustering of LTR arrays was performed on each assembly followed by cross-species mapping using Blast in the order PMAN >PCAL >PERE >PLEU; LTRs with a query cover >80% and identity score >80% were defined as belonging to the same class. Bottom: selection criteria for LTR group validation against the global clustering approach (one array located in chromosomes from at least two different species assemblies). **B**: Global clustering classification of LTR classes and example of comparative analysis with assembly-based classification for four selected classes.

score >80% in other assemblies were designated as a sub-class from that class. Clusters with values below the cut-offs maintained their primary classification (**Figure 3A**).

The clustering analysis was able to generate groups based on previous and newly identified LTR classes (**Table 4**). The assemblies that showed a higher percentage of clustered LTRs were the PMAN 2.1 CONTIGS and PCAL. The PERE assembly has the smallest percentage of clustered LTR groups, while the PMAN 1.0, PMAN 2.1 CHR and PLEU assemblies have at least half or more of their LTRs detected clustered in groups. Furthermore, the clustered groups of all assemblies were mostly composed of PMSat arrays. Interestingly, the PCAL assembly appears to contain a higher percentage of the newly identified LTR classes, LTR_PMAN_1 and LTR_PMAN_2, in comparison with the other assemblies.

Table 4 – Clustering overview of different assemblies of *Peromyscus* genus genomes, based on similarity. Count of arrays, % of arrays, number of classes and sub-classes for each group of clustered LTRs and for orphan LTRs, corresponding to each genome. Only LTR classes that are present in 2 or more assemblies were selected.

In addition to the PMSat satellite class detected in all assemblies, there were also other two satellite classes that were detected in clustered LTRs, MurSatRep1 and MMSAT4, although in much lower count. Nevertheless, the number of arrays from these LTR classes was found to be similar across assemblies.

Transposable elements (TE) arrays were also detected within clustered groups, pertaining to the L1_Mur2_orf2, L1_Mur3_orf2, B1_Mus1/2, RMER1C and Lx5c_3end classes. The distribution of these classes was significantly different across assemblies (**Table 4**). All TE classes were found in the PMAN 2.1 CHR assembly, except for the Lx5c_3end, which was only found in the PERE and PLEU assemblies. Distinctively, in the PCAL assembly no TE arrays were found, while in the PMAN 2.1 CONTIGS only B1_Mus1/2 arrays were found, which may be due to the sequencing and assembly methods, considering all other assemblies had several TE classes detected.

Some of the newly identified LTRs classes did not show significant variation in the number of arrays detected between assemblies (**Table 4**). However, the LTR_PMAN_1 and LTR_PMAN_2 classes had a very high number of arrays detected in the PCAL assembly, in comparison with the other assemblies.

Considering the identification of several highly similar LTR classes across different species described above, it was important to perform a global clustering analysis of LTRs from all assemblies. This alternative method aimed to support the robustness of the assembly-focused approach described above and to confirm the classification of orphan LTRs (**Table 5**).

Table 5 – Clustering overview of joint clustering of LTRs from all assemblies of *Peromyscus* genus genomes and the total from individual clustering of LTRs from assemblies, based on their similarity. Count of arrays, % of arrays, number of classes and sub-classes for each group of clustered LTRs and for orphan LTRs, corresponding to joint and total individual clustering. Only LTR classes that are present in 2 or more assemblies were selected.

Overall, results appear concordant with the initial grouping based on BLAST. Four classes from three different assemblies containing arrays found in chromosomes were selected for a detailed comparison between the two approaches, confirming the robustness of the proposed classification (**Figure 3B**).

LTR classes identified by the two approaches were essentially overlapping, with some orphan LTRs from the assembly-centered analysis being clustered with other groups in the global approach (**Supplementary Table 1-7**). A few LTRs did not cluster to their original group regarding the LTR_PERE_10 class. The global clustering analysis further identified ten new classes that had not been established previously (**Supplementary Table 7**).

The clustering analysis successfully identified LTR groups, including those not previously described in the Dfam database, which were named according to the aforementioned methods. Furthermore, it was possible to conclude that PMSat was the most predominant LTR class across all assemblies. The results also demonstrated the presence of highly similar LTR arrays across species, further confirming the widespread distribution of specific LTR classes in the *Peromyscus* genomes.

3.1.4 PMSat array variations between different *Peromyscus* species

After establishing the major presence of PMSat arrays across all *Peromyscus* species, it was relevant to assess similarities and differences in array sequence and structure PMSat across assemblies. For that purpose, monomer length, GC-content, and array length were determined (**Figure 4-6**). The monomers of PMSat arrays are most predominantly with 345 bp across assemblies, however, the GC-content seems to be different (**Figure 4**). To analyze these differences, a ANOVA One-way statistical test was performed to detect significant differences of monomer length and GC-content of PMSat monomers across the four species. A statistically significant difference was found across the four Peromyscus species in average monomer length ($F(3)=12.1$, $p < 0.001$). A Tukey post-hoc test was also performed to assess the significant pairwise differences between genomes, regarding PMSat monomer length. This test revealed significant pairwise differences between assemblies, except between the PMAN and PLEU assemblies, and between the PCAL and PERE assemblies (**Supplementary Table 1A**). Furthermore, the mean of monomer length across all assemblies is ~345 bp (**Figure 5A**). Regarding the average monomer GC-content, a statistically significant difference was found between the four species ($F(3) = 271.5$, $p < 0.001$). The Tukey post-hoc test revealed significant pairwise differences between assemblies, except between the PERE and PLEU assemblies (**Supplementary Table 1B**). Furthermore, the mean of GC-content of PMSat monomers from the PCAL assembly is closer to 45%, from the PERE and PLEU assemblies closer to 44%, and from the PMAN assembly closer to 43% (**Figure 5B**).

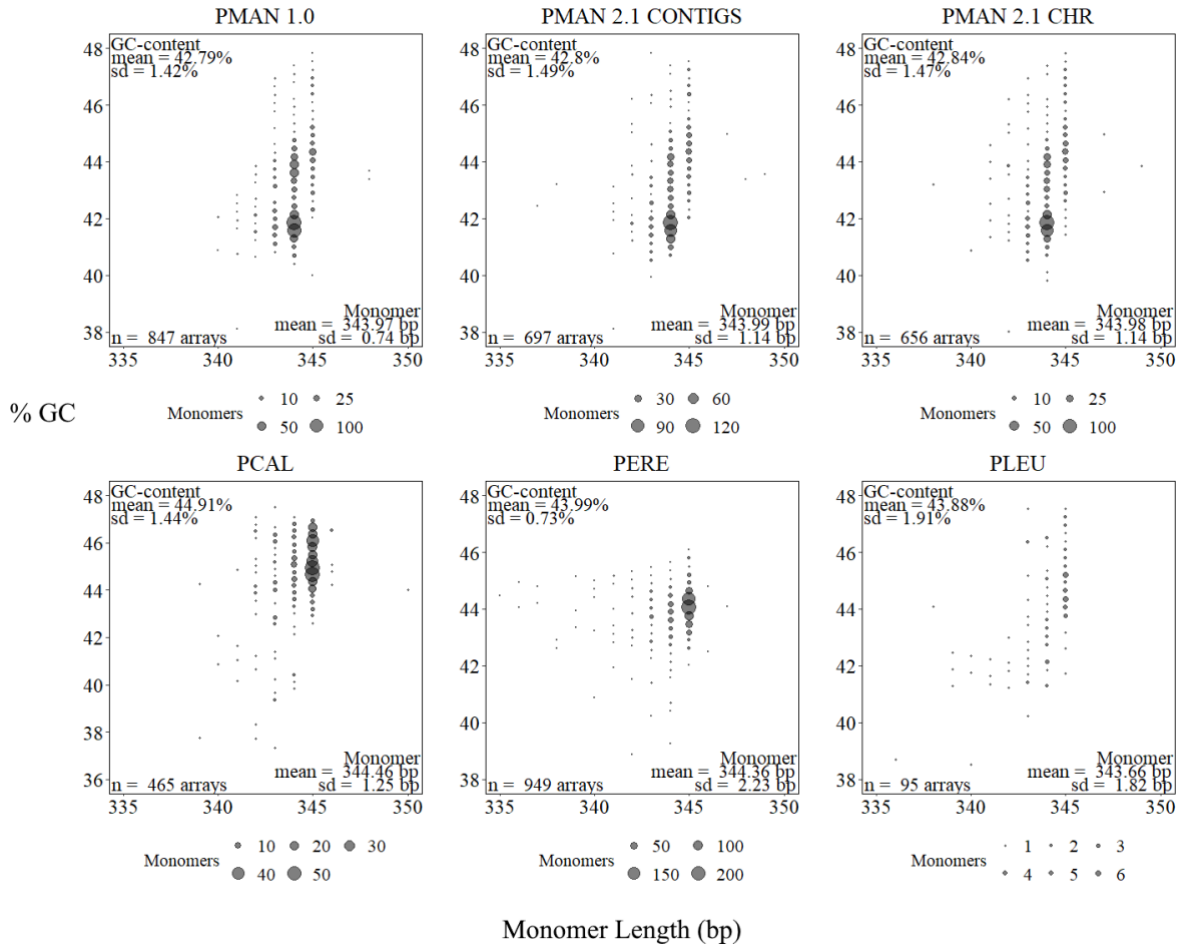

Figure 4 – Distribution of % monomer GC-content and monomer length (bp) in *Peromyscus* PMSat arrays.

The PMSat arrays have varied lengths and GC-content across all *Peromyscus* assemblies (**Figure 6**). A statistically significant difference was found across the four Peromyscus species in average array length ($F(3)=32.03$, $p < 0.001$). The Tukey post-hoc test revealed significant pairwise differences between assemblies, except between the PMAN and PCAL assemblies, and between the PERE and PLEU assemblies (**Supplementary Table 1C**). Furthermore, the mean array length of PMSat arrays from the PERE and PLEU assemblies is higher than the PMAN and PCAL assemblies (**Figure 5C**). Regarding the average array GC-content, a statistically significant difference was found between the four species ($F(3)=283.8$, $p < 0.001$). The Tukey post-hoc test revealed significant pairwise differences between assemblies, except between the PERE and PLEU assemblies, similar to the differences in mean levels of PMSat monomer GC-content (**Supplementary Table 1D**). Furthermore, the mean GC-content of PMSat arrays from the PCAL assembly is closer to 43%, from the PERE and PLEU assemblies closer to 42%, and the PMAN assembly closer to 41% (**Figure 5D**).

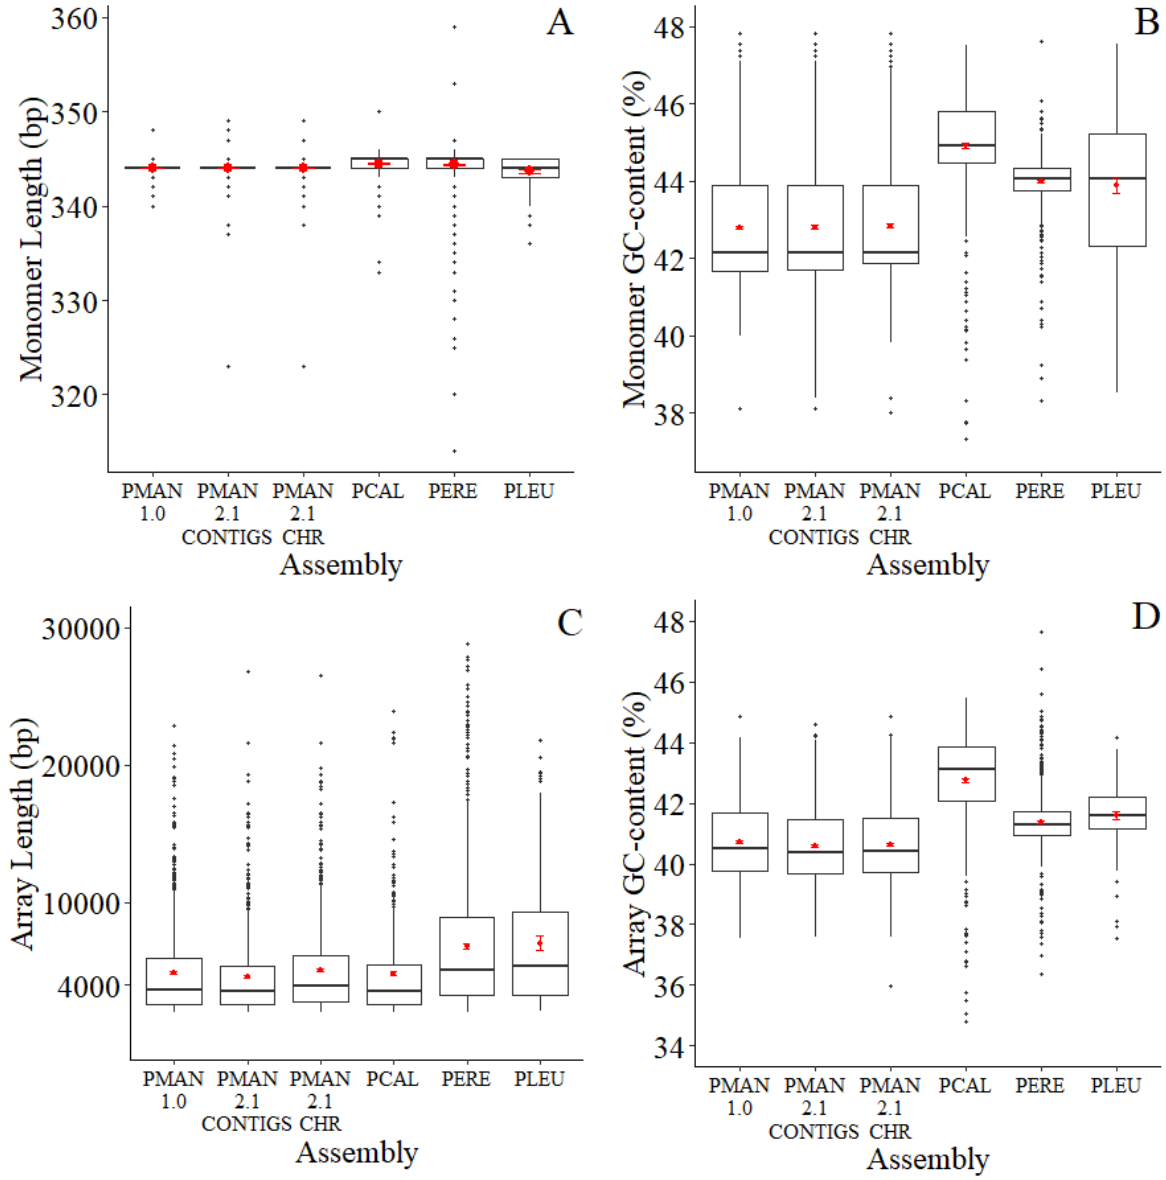

Figure 5 – Boxplot of PMSat monomer length (A), monomer GC-content (B), array length (C) and array GC-content (D) across the assemblies. Red dot represents the mean value, while the red error bars represent the standard error of the mean.

The analysis of PMSat arrays in the four *Peromyscus* species revealed that the mean monomer length predominantly remains consistent at 345 bp across assemblies, while slight differences exist in monomer GC-content among the four species. Additionally, the PMSat array mean GC-content also slightly varied among the four species, while PMSat array length showed significant differences among them, with PERE and PLEU having a higher mean array length in comparison with PMAN and PCAL. This might provide further insight into the relative positioning of PMSat arrays across the *Peromyscus* genomes.

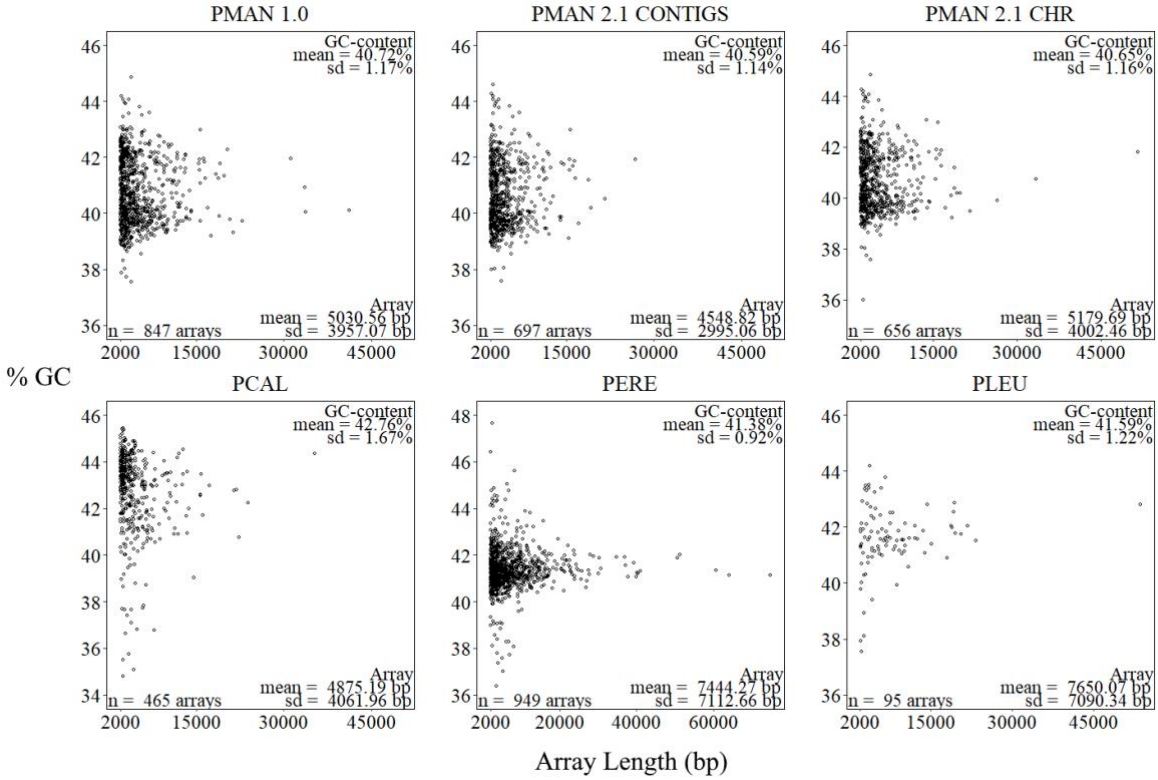

Figure 6 – Distribution of % array GC-content and array length (bp) in *Peromyscus* PMSat arrays.

3.1.5 Relative positioning of PMSat and other LTR arrays in *Peromyscus* spp. chromosomes

To further improve the annotation of LTR classes in the *Peromyscus* genus, the chromosome length of the four *Peromyscus* genomes (**Supplementary Table 8**) was used for LTR mapping on those chromosomes based on their coordinates of detection (**Supplementary Table 9**). Furthermore, by selecting a monomer of a LTR from each class and comparing its relative orientation to other LTRs (LTR in bold – **Supplementary Table 9**), it was possible to accomplish a global arrangement of LTR relative position and orientation. Additionally, cluster groups were added to this table based on the order in which class in the joint clustering table was established (**Supplementary Table 7**) (for example, as seen for the MMSAT4 class, which has 3 sub-classes, has also 3 cluster groups, 18, 33, and 47). The results obtained are described in the following subsections by LTR class.

3.1.5.1 Arrangement of PMSat arrays relative to their position on chromosomes in *Peromyscus* spp.

Chromosome 1 contains the majority of PMSat arrays detected in the PCAL and PERE assemblies, while chromosome 22 of the PMAN and PLEU assemblies contains the most PMSat arrays detected (**Supplementary Table 10**). The results of the positioning are presented in **Figure 7**. Some patterns appear to be similar between assemblies, such as the configuration of PMSat arrays in chromosome 13 for PMAN and PCAL, containing similar number of arrays and the same orientation,

although with distinct array lengths in comparison (**Supplementary Table 9**). Other patterns are difficult to outline, considering the different positioning and orientation of these PMSat arrays.

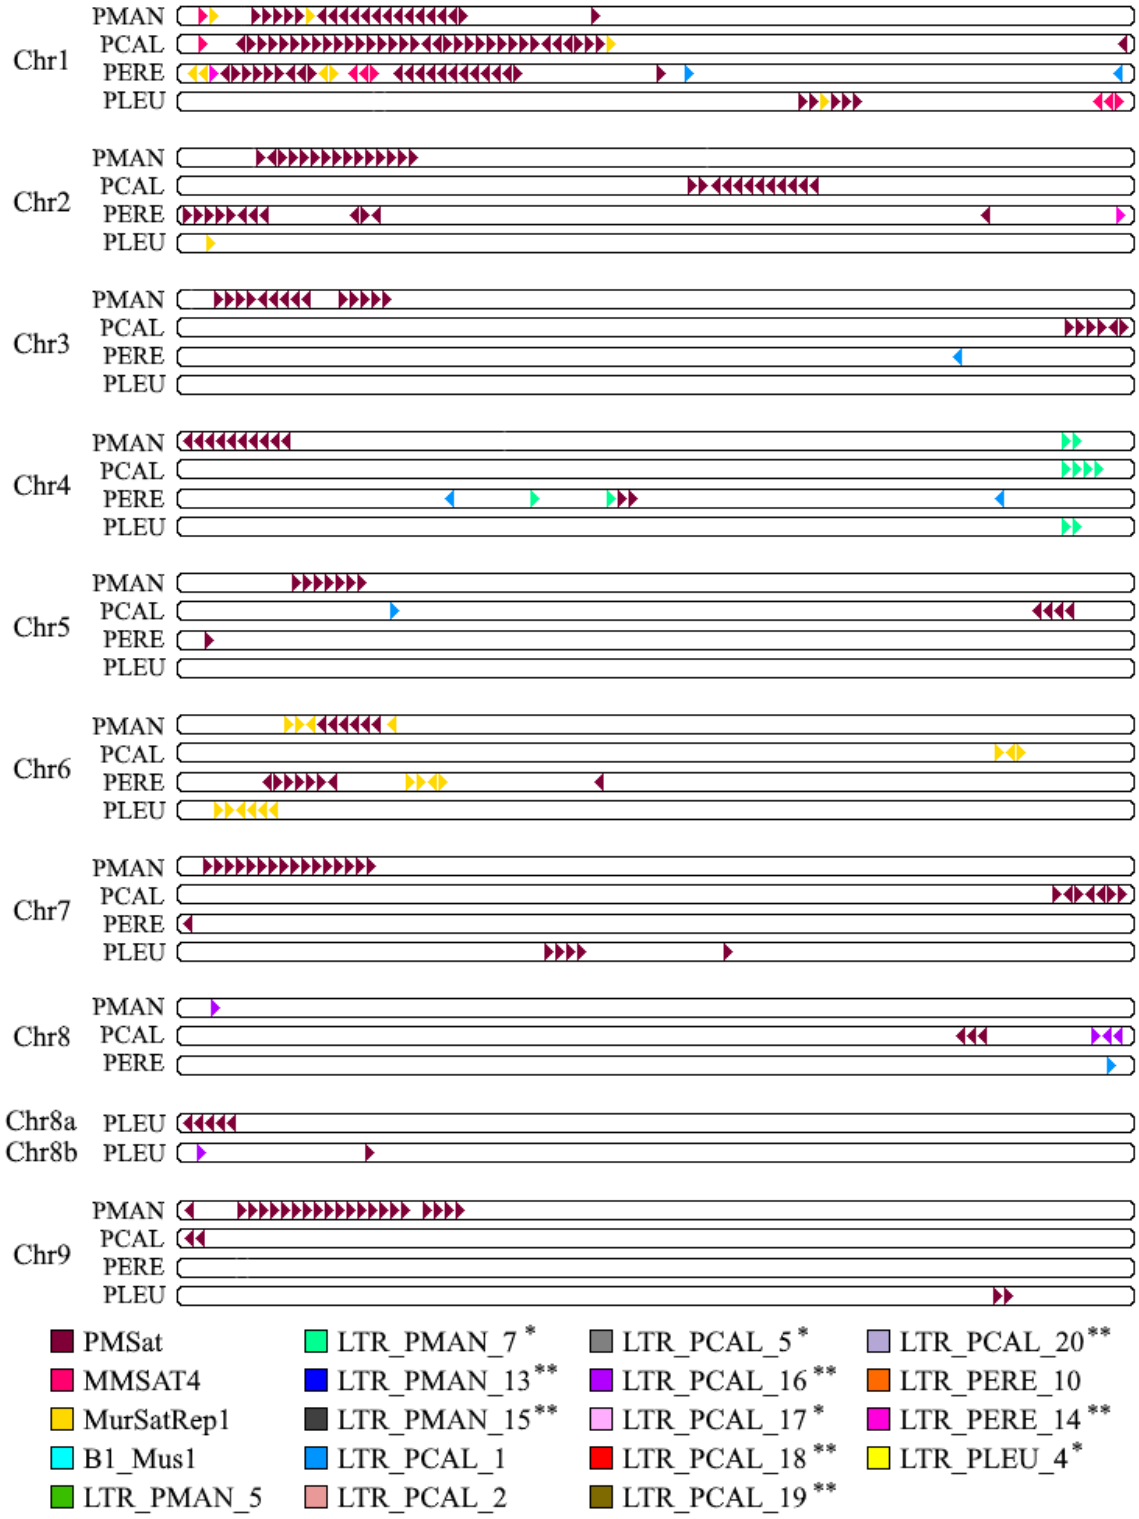

Figure 7 – Orientation and relative positioning of clustered LTR classes from *Peromyscus* genus. LTR arrays are represented on chromosomes matching each *Peromyscus* genome assembly. Each LTR array was placed based on the relative position of the coordinates of where it was detected and designated based on its LTR class. * These LTRs were not previously detected on chromosomes from at least 2 different species. ** These were new LTR groups clustered from joint clustering and followed the conditions established for relative positioning in **Figure 3**.

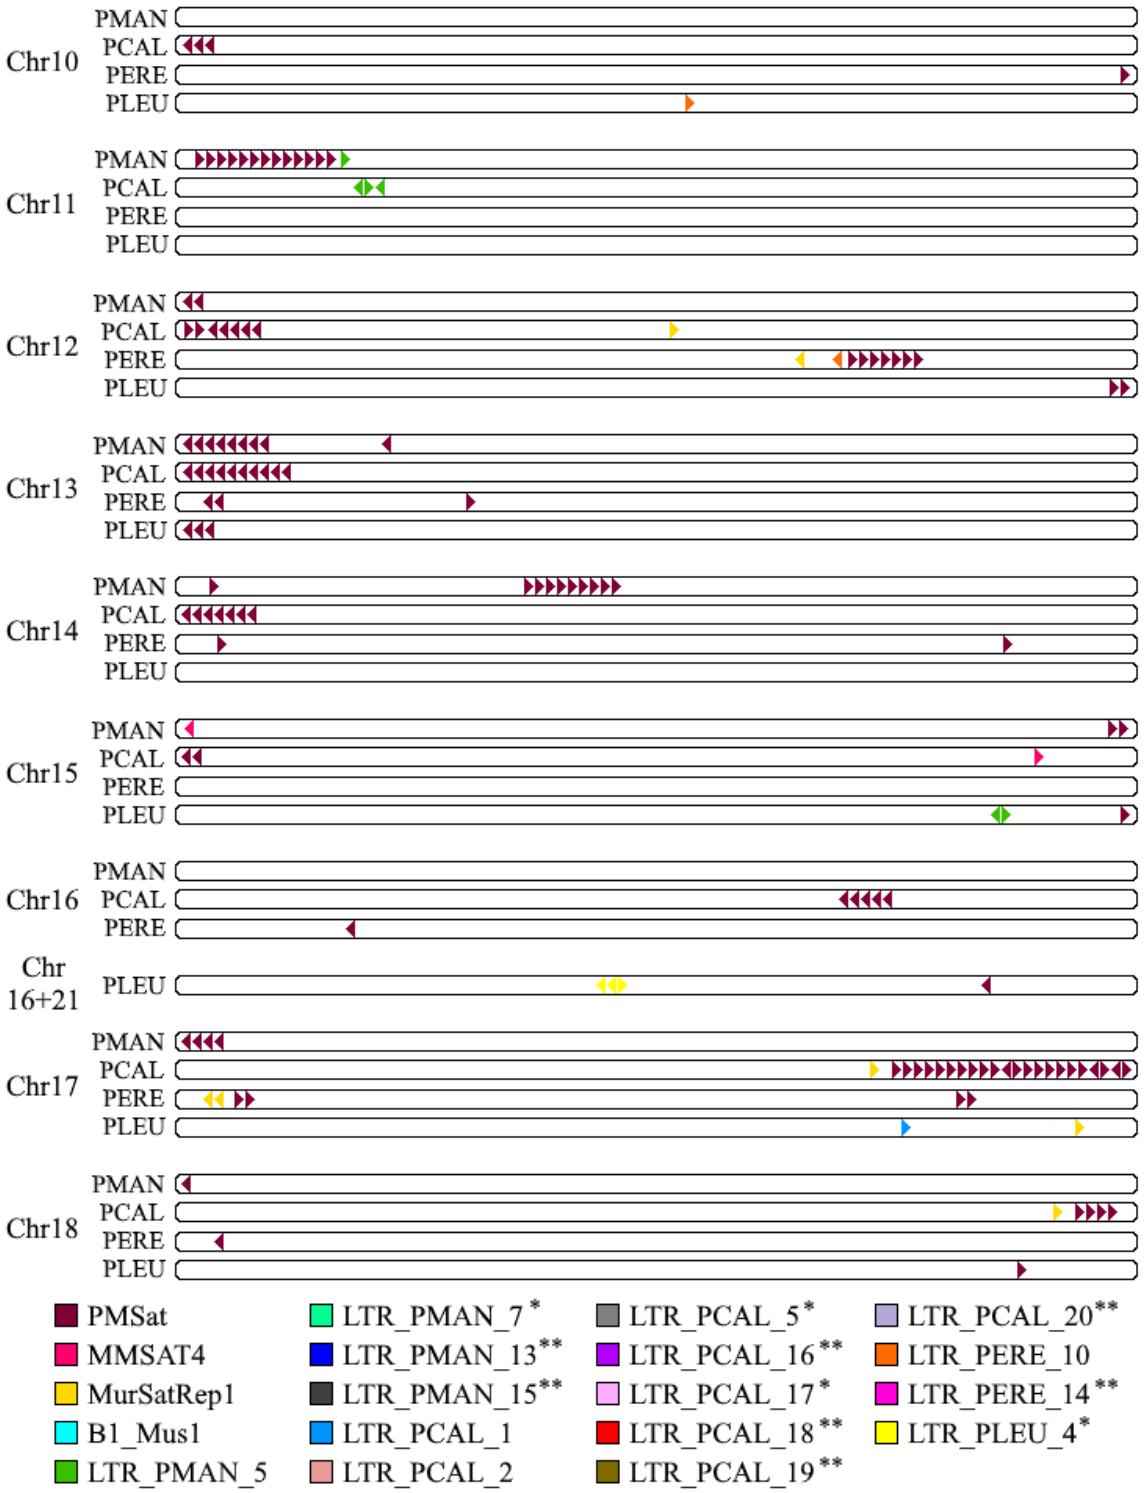

Figure 7 (cont.) – Orientation and relative positioning of clustered LTR classes from *Peromyscus* genus. LTR arrays are represented on chromosomes matching each *Peromyscus* genome assembly. Each LTR array was placed based on the relative position of the coordinates of where it was detected and designated based on its LTR class. * These LTRs were not previously detected on chromosomes from at least 2 different species. ** These were new LTR groups clustered from joint clustering and followed the conditions established for relative positioning in **Figure 3**.

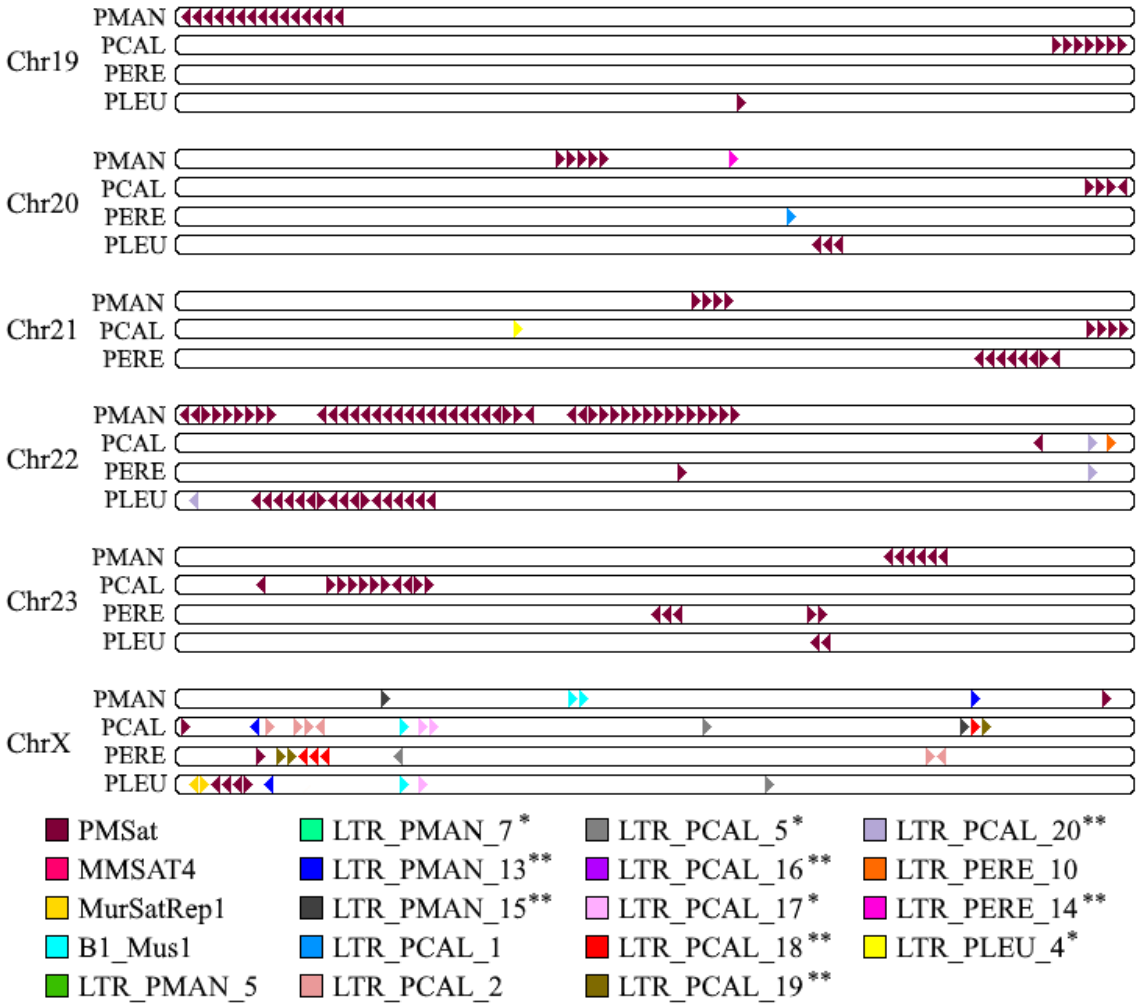

Figure 7 (cont.) – Orientation and relative positioning of clustered LTR classes from *Peromyscus* genus. LTR arrays are represented on chromosomes matching each *Peromyscus* genome assembly. Each LTR array was placed based on the relative position of the coordinates of where it was detected and designated based on its LTR class. * These LTRs were not previously detected on chromosomes from at least 2 different species. ** These were new LTR groups clustered from joint clustering and followed the conditions established for relative positioning in **Figure 3**.

Considering this, another clustering analysis was performed with the MeshClust tool (Girgis, 2022), in order to understand the connection between each PMSat monomer. This clustering method is based on identity scores without alignment, which could help in this case, considering these are highly repetitive sequences. A group of PMSat monomers clustered was selected and then their arrays represented in their relative localization on their respective chromosomes from all assemblies (**Figure 8**). PMSat arrays from this clustered group are located on two chromosomes in the PMAN assembly, on four chromosomes in the PCAL assembly, and on three chromosomes in the PERE assembly. There seems to be a pattern of the arrays being orientated on the minus strand, for the monomers in this selected clustered group. Additionally, there seems to be a prevalent pattern of two arrays on chromosome 12 on the PMAN and PCAL assemblies, however, they have slightly distinct array lengths, with the upstream from both PMAN and PCAL being ~3200 bp and ~3900 bp, respectively, and the downstream being ~3100 bp and 6000 bp, respectively (**Supplementary Table 9**; **11**). Furthermore, three of the arrays within this group seem to be positioned relatively closer to the end of the chromosome, contrary to the more common position closer to the start of chromosomes. One array is located on chromosome 5 in the PCAL assembly, and two arrays are located on chromosome 21 in the PERE assembly.

Figure 8 – Orientation and relative localization of cluster group 1 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

Other PMSat clustered groups also showed interesting arrangement connection on chromosomes from the four *Peromyscus* genus assemblies (**Supplementary Figure 2-16**). Some PMSat clustered groups seem to be distributed across all four assemblies (**Supplementary Figure 2; 8**), with some groups showing a higher connection between the PCAL and PERE assemblies (**Supplementary Figure 3-4; 6**), another group showing connection between the PCAL, PERE and PLEU assemblies (**Supplementary Figure 5**), some groups showing a higher connection between the PMAN and PLEU assemblies (**Supplementary Figure 10-11; 13-15**), and some only showing presence mostly in the PMAN assembly (**Supplementary Figure 12; 16**). Some groups do not show significant connection due to their low number of arrays present within their respective group (**Supplementary Figure 7; 9**). Some PMSat arrays within each group have a varied relative positioning on chromosomes within and outside each assembly (**Supplementary Figure 2-7; 10; 14-15**), while others appear to be predominantly located on a specific region of the chromosomes within and outside each assembly (**Supplementary Figure 8-9; 11-13; 16**).

From these observations, it was possible to conclude that PMSat arrays have variable arrangements across all genomes, although some still retain similar arrangements in specific chromosomes. This might provide further insight into the connection of other LTR classes across the *Peromyscus* genomes.

3.1.5.2 Arrangement of novel LTR arrays relative to their position on chromosomes in *Peromyscus* spp.

To further increase the knowledge of the connections regarding other LTR classes in chromosomes of these *Peromyscus* species, the classes LTR_PMAN_5, LTR_PCAL_1, LTR_PCAL_2 and LTR_PERE_10 were initially selected for relative positioning analysis in chromosomes, due to the LTRs detected in their groups being present in the individual LTR detection analysis in chromosomes from different assemblies (see **Figure 3**). However, upon performing joint clustering analysis of LTRs from all assemblies additional extra LTR arrays from previous defined classes, and new LTR classes mentioned in section **3.2** were also considered for relative positioning mapping (**Figure 7**). The LTR arrays from the initial identified four classes within **Figure 3** conditions, LTR_PMAN_5,

LTR_PCAL_1, LTR_PCAL_2 and LTR_PCAL_10 classes demonstrate distinguishing chromosomic configurations within their classes.

The LTR_PMAN_5 arrays shown on chromosome 11 of the PMAN and PCAL assemblies are closer to the start of chromosome, while on chromosome 15 of the PLEU assembly they are shown to be closer to the end of chromosome (**Figure 7**). Interestingly, the monomer of this class is of smaller length (~63 bp), similar to the size of satellite sequences (**Supplementary Table 7**). Moreover, one the arrays in the PMAN, PCAL and PLEU assemblies has similar lengths (~15,000-16,000 bp), though it is on the plus strand in chromosome 11 of the PMAN assembly and in chromosome 15 of the PLEU assembly, while in chromosome 11 of the PCAL assembly it is on the minus strand (**Figure 7**). Additionally, another array of ~55,000 bp is also common in chromosome 11 of the PCAL assembly and chromosome 15 of the PLEU assembly, with the same orientation on the minus strand. Distinctively, while the distance between the arrays with ~55,000 bp and ~16,000 bp in the PCAL assembly is ~115 kbp, the distance between the similar arrays in the PLEU assembly is ~1.3 Mbp (**Supplementary Table 9**).

Concerning the LTR_PCAL_1 class, their lengths and orientations are different from the ones detected in the chromosomes of the PCAL assembly. The array in the PCAL assembly has a copy number of ~18, while in the PERE and PLEU assemblies the arrays have a copy number of ~2-3. Moreover, the arrays are localized in distinct chromosomes in the PERE assembly (1, 3, 4, 8 and 20), while in the PCAL assembly only being detected on chromosome 5 and in the PLEU assembly on chromosome 17. The monomer length of this class ranges from 1025-1865 bp (**Supplementary Table 7**). It does not seem to show a preferable orientation or localization (**Figure 7**).

Regarding the LTR_PCAL_2 class, it was only detected in chromosome X in two of the *Peromyscus* genomes (**Figure 7**). There are four arrays closer to the start of chromosome X in the PCAL assembly, while only two arrays are closer to the end of chromosome X in the PERE assembly. The monomer length of this class ranges from 1707-1784 bp (**Supplementary Table 7**). Only one pattern concerning the orientation is prevalent in both assemblies, being that of the two arrays closely together and on opposite strands, the one upstream being on the plus strand, while the other downstream being on the minus strand (**Figure 7; Supplementary Table 9**). However, their lengths are distinct between them, whereas in the PCAL assembly, the one upstream and on the plus strand has ~5100 bp, while in the PERE assembly, the one upstream and also on the plus strand has ~7600 bp. The one array downstream and on the minus strand in the PCAL assembly has ~8700 bp, while in the PERE assembly, the most downstream array and on the minus strand has ~5000 bp (**Figure 7; Supplementary Table 9**).

LTR_PERE_10 class seems to also have monomers of higher length ranging with 1398-1980 bp, however, there is only one array detected on distinct chromosomes of the PCAL, PERE and PLEU assemblies (**Figure 7; Supplementary Table 9**). In chromosome 22 of the PCAL assembly, its array is closer to the end of the chromosome and on the plus strand (**Figure 7; Supplementary Table 9**). In chromosome 12 of the PERE assembly, its array seems to be located on the middle part of the end of the chromosome and on the minus strand (**Figure 7; Supplementary Table 9**). In the PLEU assembly was located around the middle region in the chromosome 10 and on the plus strand (**Figure 7; Supplementary Table 9**). Additionally, all of these arrays have different lengths, with ~4100 bp, ~2800 bp and ~6000 bp in the PCAL, PERE and PLEU assemblies, respectively (**Supplementary Table 9**).

There were also more classes that previously did not show any LTRs being detected on chromosomes that after joint clustering revealed to be present. One of these was the LTR_PMAN_7 class. With a monomer length of 69 bp, it was detected only in chromosome 4 of all four genomes. Moreover, it was on the plus strand of all four genomes (**Figure 7**). Although all of the arrays varied in

length, ranging with ~3400-16,000 bp, there was a similar array in the PMAN and PLEU assemblies, with ~16,000 bp (**Supplementary Table 9**).

LTR_PCAL_5 class also had new arrays added to its cluster group that were detected in chromosomes. Specifically in this one, the arrays were detected in chromosome X of the PCAL, PERE and PLEU assemblies (**Figure 7**). The monomer length of this class is ~310 bp (**Supplementary Table 7**). Although on different strands, there is one array in the PCAL assembly similar in length to that of the one in the PERE assembly, with ~3300-3800 bp, and also with similar localization in the chromosome (**Figure 7**; **Supplementary Table 9**). The array in the PCAL assembly is much larger in length, with ~29,000 bp and closer to the start of the chromosome.

LTR_PCAL_17 class also had additional arrays detected in other assemblies. This class also only had arrays detected in chromosome X, however, in this case exclusive to the PCAL and PLEU genomes (**Figure 7**). The monomer length is 51 bp (**Supplementary Table 7**). These arrays were only on the plus strand and in similar localization in the chromosome X of these genomes (**Figure 7**). The length of the two arrays detected in the PCAL assembly are of smaller size (~2500 bp and 4000 bp) compared to the one array detected in the PLEU assembly (~12,000 bp) (**Supplementary Table 9**).

LTR_PLEU_4 class also had more arrays detected after joint clustering of all assemblies. The monomer length ranged from 1554-1601 bp (**Supplementary Table 7**). All of the arrays detected were located near the middle of chromosome 21 in the PCAL assembly and chromosome 16+21 in the PLEU assembly (**Figure 7**). Additionally, the array detected in the PCAL assembly is on plus strand, while the three arrays detected in the PLEU assembly are on the minus>minus>plus order (**Figure 7; Supplementary Table 9**).

Regarding the new classes of LTRs identified based on the joint clustering analysis, there were the LTR_PMAN_13, LTR_PMAN_15, LTR_PCAL_18 and LTR_PCAL_19 classes that showed to only have arrays in chromosome X. The monomer length of these classes is ~72 bp, ~72 bp, 77 bp and 126-168 bp, respectively (**Supplementary Table 7**). The LTR_PMAN_13 class detected in the PMAN assembly is on the plus strand and closer to the end of the chromosome X, while the arrays from this class detected in the PCAL and PLEU assemblies are on the minus strand and closer to the start of the chromosome X (**Figure 7**). The LTR_PMAN_15 class has arrays detected on opposite sides of the chromosome X in the PMAN and PCAL assemblies, while maintaining their orientation on the plus strand but with different array length (**Figure 7**; **Supplementary Table 9**). The LTR_PCAL_18 class was also detected on opposite sides of the chromosome X in the PCAL and PERE assemblies, having arrays with similar length (~2300-3400 bp), with the exception of one array in the PERE assembly (~28,000 bp) (**Supplementary Table 9**). The array in the PCAL assembly was on the plus strand and the three arrays in the PERE assembly were on the minus strand (**Figure 7**; **Supplementary Table 9**). The arrays from the LTR_PCAL_19 class had similar length (2700-3300 bp) (**Supplementary Table 9**) and were shown to be on the plus strand in chromosome X of the PCAL assembly, while the two arrays detected in the PERE assembly had one array on the minus strand and another on the plus strand (**Figure 7**; **Supplementary Table 9**).

Chromosome 8 of the PMAN, PCAL and PLEU assemblies also had exclusive detection of the LTR_PCAL_16 class, with one array located at the start of chromosome 8 in the PMAN assembly and chromosome 8b in the PLEU assembly, while three arrays were located at the end of chromosome 8 in the PCAL assembly (**Figure 7**). The monomer length of this class is 56 bp (**Supplementary Table 7**). Moreover, there is one array that had similar length (~2000 bp) in both the PCAL and PMAN assemblies, while only array in the PLEU assembly has a larger copy number of the monomer in its array (**Supplementary Table 9**). A similar arrangement was observed regarding the LTR_PCAL_20 class,

where it only had arrays detected on chromosome 22 (**Figure 7**). It had an array on the plus strand closer to the end of chromosome 22 in the PCAL and PERE assemblies, while the array in the PLEU assembly was on the minus strand and closer to the start of chromosome 22 (**Figure 7**). The monomer length of this class was 99 bp (**Supplementary Table 7**). Furthermore, the length of these arrays is different in PCAL, PERE and PLEU assemblies (~2400 bp, ~4000 bp and ~3000 bp, respectively) (**Supplementary Table 9**). The LTR_PERE_14 class had arrays located in different chromosomes, with one array located on the minus strand closer to the start of chromosome 1 in the PERE assembly, and another array also on the minus strand of chromosome 2 in the PERE assembly, though closer to end of the chromosome (**Figure 7**). Another array that was detected in the PMAN assembly was on the plus strand closer to the middle section of chromosome 20 (**Figure 7**). The monomer length of this class ranges with 1845-1947 bp (**Supplementary Table 7**), with the length of arrays being similar (~3700-3900 bp) (**Supplementary Table 9**).

3.1.5.3 Arrangement of MMSAT4 arrays relative to their position on chromosomes in *Peromyscus* spp.

The MMSAT4 family showed 3 sub-classes detected in chromosomes across all the assemblies. The monomer length of two of the sub-classes is ~84 bp, while the other sub-class had a length of ~168 bp (**Supplementary Table 7**). One of the sub-classes had an array on the plus strand closer to the start of chromosome 1 in the PMAN assembly, two arrays closely together on the minus strand closer to the start of chromosome 1 in the PERE assembly, and two arrays closely together on the minus strand closer to the end of the chromosome 1 in the PLEU assembly (**Figure 7**). One of the arrays on the three assemblies (PMAN, PERE and PLEU) regarding the sub-class from cluster group 18, has similar length (2100-2200 bp), while another array from the same sub-class that was upstream to the previous array in the PERE and PLEU assemblies has a larger length (3000 bp and 2500 bp, respectively) (**Figure 7; Supplementary Table 9**). The arrays of the sub-class from the cluster group 47 are only located in chromosome 1 of the PCAL, PERE and PLEU assemblies (**Figure 7; Supplementary Table 9**). In the PCAL and PERE assemblies the arrays were on the plus strand closer to the start of chromosome 1, while in the PLEU assembly, though also being on the plus strand, the array was closer to the end of chromosome 1 (**Figure 7**). The length of these arrays is similar, with 2100 bp (**Supplementary Table 9**). There seems to be an arrangement of three arrays of the MMSAT4 class on chromosome 1 in the PERE and PLEU assembly, with the two most upstream arrays belonging to the sub-class from the cluster group 18, while the array downstream of those two arrays belonging to the sub-class from the cluster group 47, and though these maintain their orientation, they are located on opposite sides of the chromosome (**Figure 7**; **Supplementary Table 9**). Moreover, the distance between them is also similar, with an interval of ~500 kbp and ~407 kbp between the first two arrays in the PERE and PLEU assemblies, respectively, and with an interval of ~362 kbp and ~285 kbp between the last two arrays of this set in the PERE and PLEU assemblies (**Supplementary Table 9**). In chromosome 15 of the PMAN and PCAL assemblies was also detected another sub-class of MMSAT4 from the cluster group 33. Although the arrays having similar length (~2200 bp), the one detected in the PMAN assembly was on the minus strand and closer to the start of the chromosome, the one detected in the PCAL assembly was on the plus strand and closer to the end of the chromosome (**Figure 7**; **Supplementary Table 9**).

3.1.5.4 Arrangement of MurSatRep1 arrays relative to their position on chromosomes in *Peromyscus* spp.

The MurSatRep1 class also had three sub-classes in all four genomes. The monomer length of two sub-classes is ~84 bp, while one of the sub-classes had varying length, with 168-269 bp (**Supplementary Table 7**). For the most abundant sub-class (from cluster group 4), there were arrays detected in chromosome 1 and 6 of the PMAN assembly, in chromosomes 6, 17 and 18 of the PCAL assembly, in chromosomes 1, 6, 12 and 17 of the PERE assembly, and in chromosomes 2, 6, 17 and X of the PLEU assembly (**Figure 7**). Particularly regarding this sub-class, there seems to be a specific arrangement in chromosome 6 of all assemblies, with one array on the minus strand with ~2100 bp, followed by an array on the plus strand with ~2900 bp (**Supplementary Table 9**). However, in the PMAN assembly this set of arrays may be inverted, as the array with ~2900 bp is upstream of the array with ~2100 bp, while also being closer to the end of the chromosome 6 (**Figure 7**; **Supplementary Table 9**). Another sub-class of MurSatRep1 was only detected in chromosome 1 of all *Peromyscus* genomes. Interestingly, the length of the arrays in this sub-class (from cluster group 17) in all the genomes was similar (~3000 bp), with exception of one array in the PERE assembly (~2100 bp) (**Supplementary Table 9**). However, these arrays have different orientation and location in the chromosomes. In the PMAN and PCAL assemblies the arrays were on the plus strand and around the middle section of the start of chromosome 1, while the array in the PERE assembly was on the minus strand and closer to the start of chromosome 1, and the array in the PLEU assembly was on the plus strand and closer to the end of chromosome 1 (**Figure 7**; **Supplementary Table 9**). There was also one sub-class that only had one array located in chromosome 12 of the PCAL assembly, on the plus strand and in the middle section of the chromosome (cluster group 46) (**Figure 7**; **Supplementary Table 7; 9**).

From the relative positioning and orientation of both PMSat and other LTR classes in the chromosomes across all genomes it could be concluded that, although they have diverse arrangements, it still exists some arrays that have similarities pertaining to these characteristics across all *Peromyscus* genomes. Furthermore, the analysis of the PMSat satellite family found in the *Peromyscus* genus allowed for a detailed portrayal of its arrangements, showing that arrays with a high degree of similarity had preferential chromosome positioning across all four genomes. This analysis also revealed that these methodologies had relevant results, which might help with the exploration of LTRs in the human genome, mainly with the characterization of human satDNA families.

3.2. Improving the characterization of LTR arrays and satDNA in the human genome

This section describes the results obtained in the frame of the second objective of this project: to take advantage of the recently available Nanopore long read sequencing methodology to gain more in-depth knowledge on the organization and function of LTRs and satDNA in the human genome. The analysis of LTRs in the human genome was focused on satellite DNA, with a particular interest in assessing peri/centromeric region arrangements in chromosomes. These regions have proven difficult to characterize, namely due to their highly contiguous repetitive sequence composition (M. Aldrup-MacDonald & Sullivan, 2014; Miga, 2015; Miga et al., 2014). Consequently, highly contiguous sequencing technologies such as nanopore sequencing technology (Jain et al., 2018) have emerged and shown to be important in the characterization of long tandem repeats arrays (Kinkar et al., 2021; Vondrak et al., 2020). We took advantage of two whole genome datasets that are publicly available (NA12878 and CHM13) and one additional dataset was generated in-house by low-depth sequencing of total DNA and sorted chromosomes of the human cell line GM03417 with a ROB t(14;21) translocation to investigate the impact of unusual chromosomal rearrangement. Furthermore, an in-depth study of a specific human satellite family, HSat1A, was performed, involving genomic copy number and transcription product diversity analysis.

3.2.1 Detection and analysis of human LTRs in nanopore sequencing datasets

Concurrently with this study, nanopore sequencing was performed in-house on total DNA from the GM03417 cell line, using a total of two flowcells. This yielded a dataset of 20.3 Gbps that was analyzed in the frame of this dissertation project, corresponding to a total of 6.5x the estimated genome coverage. Sequencing metrics for the publicly available NA12878 and CHM13 and this in-house dataset were calculated for comparative purposes (**Table 6**).

Cell culture and genomic DNA isolation of cell line GM03417 containing ROB t(14;21) for Oxford Nanopore Technology (ONT) sequencing showed overall improvement on the percentage of long reads when compared to the publicly available NA12878 dataset for the same cell line and technology, with 6.27% of total reads being above 30 kbps, while the NA12878 dataset showed only 2.70% of total reads to be above 30 kbps. However, the NA12878 dataset produced a higher percentage of ultra long reads, with 0.48% of total reads being above 100 kbps, while the GM03417 dataset produced 0.03% of total reads being above 100 kbps. The CHM13 dataset showed better overall results (**Table 6**).

Table 6 – Overview analysis of the GM03417 cell line and the NA12878 and CHM13 datasets. Quantification and distribution of raw reads belonging to each dataset**.** Additional ratios were analyzed based on each relevant category (30 kbp, 100 kbp) relative to the total reads. Sequencing coverage was also performed relative to the total bases and relative to the > 30 kbp reads. Gpb per flow cell was measured based on the total Gbp detected versus the number of runs (flow cells) performed.

	GM03417	NA12878	CHM13

Runs (flow cells)	2	52	481
Gbp per flow cell	10.15	2.56	0.74

Detection of tandem repeats in raw reads above 30 kbps was the selected method for this analysis with the Tandem Repeat Finder tool (Benson, 1999), in an effort to assess the LTR detection performance after sequencing on long contiguous reads. Moreover, investigation of LTR diversity largely found in peri-centromeric and centromeric regions was the focus of this analysis, comparing between the sequencing data of the GM03417 cell line and the other two cell lines without chromosomal abnormalities (GM12878 and CHM13). When comparing the detection of LTRs in the GM03417, NA12878 and CHM13 datasets, the latter showed a much higher number of detected arrays (**Table 7**).

Table 7 – Quantification of nucleotide sum from LTR arrays detected on GM03417, NA12878 and CHM13 datasets.

	GM03417	NA12878	CHM13
Total nt from reads (bp)	20,302,191,845	132,931,102,331	357,422,186,747

% LTR arrays nt sum/Total nt from reads	0.52	0.40	2.11

Following this, a clustering analysis with blastclust (Altschul et al., 1990) was performed on the LTRs detected (**Supplementary Table 11-13**). The top 20 clustered groups regarding number of detected arrays from each dataset and corresponding to > 93% of all LTRs in clustered groups, were selected to simplify this analysis while maintaining a broad number of LTR groups.

A sequence search was performed using Dfam (Hubley et al., 2016; Storer et al., 2021) to identify known repetitive sequences, corresponding to each group. The results from this analysis are presented in **Table 8** and are discussed in detail next.

Table 8 – Clustering overview of the top first 20 clustered groups of LTRs from GM03417, NA12878 and CHM13 datasets. Count of arrays, % of arrays, number of classes and sub-classes for each group of clustered LTRs and for orphan LTRs, corresponding to each dataset, from the top first 20 clustered groups (**Supplementary Table 11-13)**. TE – Transposable Element. RE – Repetitive Element.

In all datasets, the majority of LTRs could be grouped in clusters, with the most abundant groups corresponding to satellite sequences. The ALR (Human alpha satellite) was the most abundant LTR detected, as expected, reaching above 50% of all LTRs detected in the GM03417 and CHM13 dataset,

and almost 40% for NA12878. The BSR (Beta satellite repeat) was the second most abundant LTR detected in the NA12878 and CHM13 dataset, however, slightly below HSAT2 percentage in the GM03417 dataset. HSAT1A (SAR) and HSAT2 were slightly less abundant, with a major distinction in CHM13, that had larger abundance of HSAT2 detected in comparison to HSAT1A (~7%). Interestingly, the HSAT2 family had four and three sub-classes detected in the GM03417 and NA12878 datasets, respectively, while the CHM13 dataset only had one.

Other satellites, such as CER, ACRO1 and SST1, were detected in all datasets, but in lower count in comparison (**Table 8**). The HSAT4, GSATII and SATR1 satellites were not detected in the GM03417 and NA12878 datasets, only in the CHM13 dataset. Some transposable elements were detected, with the L1 retrotransposon family being the major represented family in this category. Moreover, some repetitive elements were detected in all 3 datasets (MER5A1r), while some were only detected in the GM03417 dataset (teucerv2_3edge) and others only in the CHM13 dataset (Walusat). NA12878 and CHM13 were the only datasets to show arrays of simple repetition elements within the first 20 groups, containing four and one sub-classes, respectively.

Un-identified LTR groups (i.e., not described in the Dfam database) were compared using the BLAST tool (Z. Zhang et al., 2000) to identify similar groups across datasets and named in decreasing order of group size (H_LTR_1 to H_LTR_6). The H_LTR_1, H_LTR_2, H_LTR_4 and H_LTR_5 groups were detected in all the three datasets. However, the H_LTR_3 group was only detected in the GM03417 and CHM13 datasets, while the H_LTR_6 group was only present in the NA12878 dataset.

Additionally, it was of interest to assess if there were any differences in regards to satDNA detection on chromosomes 14 and 21 from the GM03417 cell line, which has the translocated chromosome t(14;21), with the other two cell lines without chromosomal abnormalities (GM12878 and CHM13 datasets). For this, alignment of reads containing at least one of the top four satDNA clustered groups (ALR, BSR, HSat2 and HSat1A) with chromosome 14, 21 or both from the human genome assembly GRCh38.p13 was performed (**Table 9**). There are no apparent significant percentual distinctions between the three datasets, which could indicate insufficient data from the GM03417 cell line in order to assess the translocation t(14;21).

This analysis allowed to show the capacity of nanopore sequencing for the detection and characterization of long tandem repeats (LTRs), as with fewer flowcells used, it was still possible to produce similar results in percentage. LTR analysis revealed the dominance of satellite sequences present in each dataset, albeit with some differences in percentage across the datasets. Furthermore, when assessing satDNA detection on chromosomes 14 and 21, no apparent differences were observed among the datasets, which a flow-sorting of chromosomes might prove beneficial for the analysis of translocation t(14;21).

Table 9 – Alignment of reads from each dataset to chromosomes 14 and 21 from reference human genome GRCh38.p13. The first row of each dataset indicates the number of reads that aligned with each chromosome or the combination of both (chromosome 14 and 21). The percentage calculation is based on the number reads that aligned with each chromosome or both. Each satDNA selected for this analysis was based on the top 4 clustered groups from each dataset (**Supplementary Table 11-13**).

3.2.2 Assessment of sequencing data from flow sorted chromosomes of the ROB t(14;21) GM03417 cell line

A different approach was taken to improve on the coverage limitation of the sequencing performed to study the ROB t(14;21) on the GM03417 cell line. Flow Cytometry (flow-sorting) of chromosomes has shown great progress in their isolation and enrichment to simplify assembly and study of individual chromosomes (Cápal et al., 2016; Doležel et al., 2021; Kuderna et al., 2019). This technique relies on chromosome size for discrimination. As a consequence, some groups of chromosomes will be sorted together, with translocated chromosome rob(14:21) being captured along with chromosomes 9, 10, 11, and 12.

Flow-sorting of chromosomes to capture rob(14:21) was performed on the GM03417 cell line, following Kuderna et al. protocol. Subsequently, sequencing was performed using ONT on these flow-sorted chromosomes, with the same intent as before. In this pilot assay, 330,000 chromosomes were isolated, which is 10x less than the referenced number by Kuderna et al. Notwithstanding, the flow-sorting and sequencing performed was successful, as 182 of the 226 reads that were obtained showed

alignment with the intended flow-sorted chromosomes (**Figure 9**). Moreover, the mean length of the reads was ~1790 bp, with read length ranging from 124 bp to 16,777 bp. Unfortunately, due to the low sequencing data yield, further analysis to characterize the translocated region was not possible.

Although the low sequencing data yield did not allow for the study of the ROB t(14;21) in the GM03417 cell line, it was still possible to conclude that these methods are able to provide an improvement to chromosome coverage, albeit with the sufficient quantity of flow-sorted chromosomes.

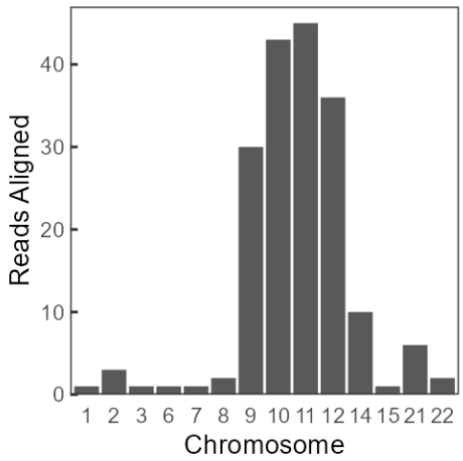

Figure 9 – Alignment of reads from flow-sorted chromosomes of nanopore sequencing on GM03417 cell line. The reads were aligned to each 24 individual chromosomes from the GRCh38.p13 genome assembly.

3.2.3 HSat1A genomic copy number and transcript analysis

As satDNA genomic occurrence and preservation seem to be associated with long-range organization and structure of peri/centromeric regions (Plohl et al., 2014), the HSAT1A satellite, which is highly present in these regions (Altemose et al., 2022), is of particular interest for our study. The human satellites have shown to be transcriptionally active (Ugarkovic, 2005), however, the role of this is still not fully understood. To further increase knowledge on these repetitive sequences, HSat1A was selected for a focused analysis to inspect its long-array structure and transcriptional activity. A previously done analysis on the CHM13 dataset with the NTRprism software tool, which was specifically developed for this purpose, reported that HSAT1A displays a higher-order organization (HOR) with the predominance of 9-mer NTRs (nested tandem repeats) (Altemose et al., 2022). To expand on this information and assess the recurrency of HSAT1A organization in an additional reference cell line, the same approach was applied to the NA12878 dataset. It was also confirmed with this analysis, that the most frequent periodicity identified corresponds to the HSat1A 42-bp monomer, followed by the 378-bp 9-mer array (**Figure 10**). Although these are the two most predominant monomers, there is still some relevant representation of other n-mer (**Figure 10**).

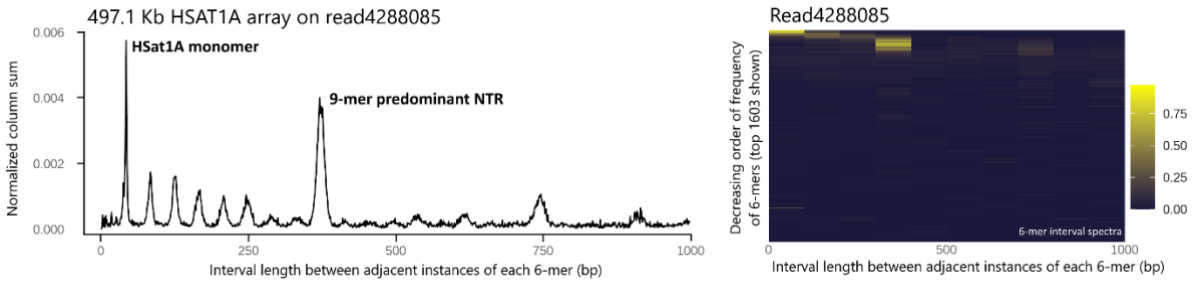

Figure 10 – HSat1A periodicity spectrum and heatmap in a selected read from the NA12878 dataset. NTRprism reveals two predominant peaks: one corresponding to HSat1A monomer and the second to a 9-mer higher repeat. (NTR – Nested Tandem Repeat).

Following this, HSAT1A transcription activity was assessed (**Figure 11**). For this, 3′ RACE (Yeku & Frohman, 2011) in HeLa RNA using an oligo-dT anchor primer for reverse-transcription and a forward PCR primer targeting the HSat1A sequence was performed by the CytoGenomics Lab. Analysis of 3′ RACE products by agarose gel electrophoresis revealed a ladder of products, with the most intense band around 550 bp (**Figure 12A**). This result suggests that HSAT1A transcripts are polyadenylated and thus likely transcribed by RNA polymerase II (Hirose & Manley, 1998). To characterize these amplified products, a 300-nt paired-end high-throughput sequencing using the Illumina MiSeq platform was performed. A total of ~2×10^5 reads **(Supplementary Table 15**) were obtained (for R1 and R2), which were quality and size filtered and assembled into ~3.5×10^4 complete 3′ RACE transcripts. Approximately 70% of these assembled transcripts presented the HSat1A motif and were distributed across a size range of 51 to ~400 nucleotides, with peaks corresponding to multiples of the 42-monomer size (**Figure 12A**). Although PCR size-amplification bias cannot be ignored, the most prevalent sequence size was ~170 nt. Within this universe, 16,332 sequences were found to be unique, attesting to the high complexity of the HSAT1A transcriptome. By analyzing sequence reads in a window of 200 nucleotides, a progressive reconstruction of longer reads by piecing together smaller ones was observed (**Figure 12B**), possibly suggesting mechanisms of alternative polyadenylation (APA). To test this theory, the structure of a representative read was examined, having found multiple alternative and non-canonical polyadenylation signals (PASs) (Tian et al., 2005), organized in a known poly(A) signal structure (Proudfoot, 2011), and cleavage sites often corresponding to the actual read lengths (**Figure 12C**). To get a better perspective of the degree of sequence variability, this dataset was clustered into groups with a minimum sequence identity of 90%, identifying a total of 257 clusters, 50 of which had more than 50 elements (**Figure 12D-E**). Subsequently, unbiased search for sequence motifs within each of the 50 mentioned clusters was performed. The obtained repeated motifs invariably compose, or were composed of, HSat1A 42 nt monomers (**Supplementary Figure 17**).

Based on the findings of this analysis, the HSat1A human satellite family revealed to have NTR arrangements in the human genome. Moreover, there is no indication that transcription of HSat1A arises from preferable *loci*, as the transcripts showed a great sequence diversity. The size variability observed within each cluster of sequences seems to be the consequence of the frequent presence of sequence elements similar to PolyA signals within the HSat1A monomer, creating multiple alternative polyadenylation sites within arrays derived transcripts.

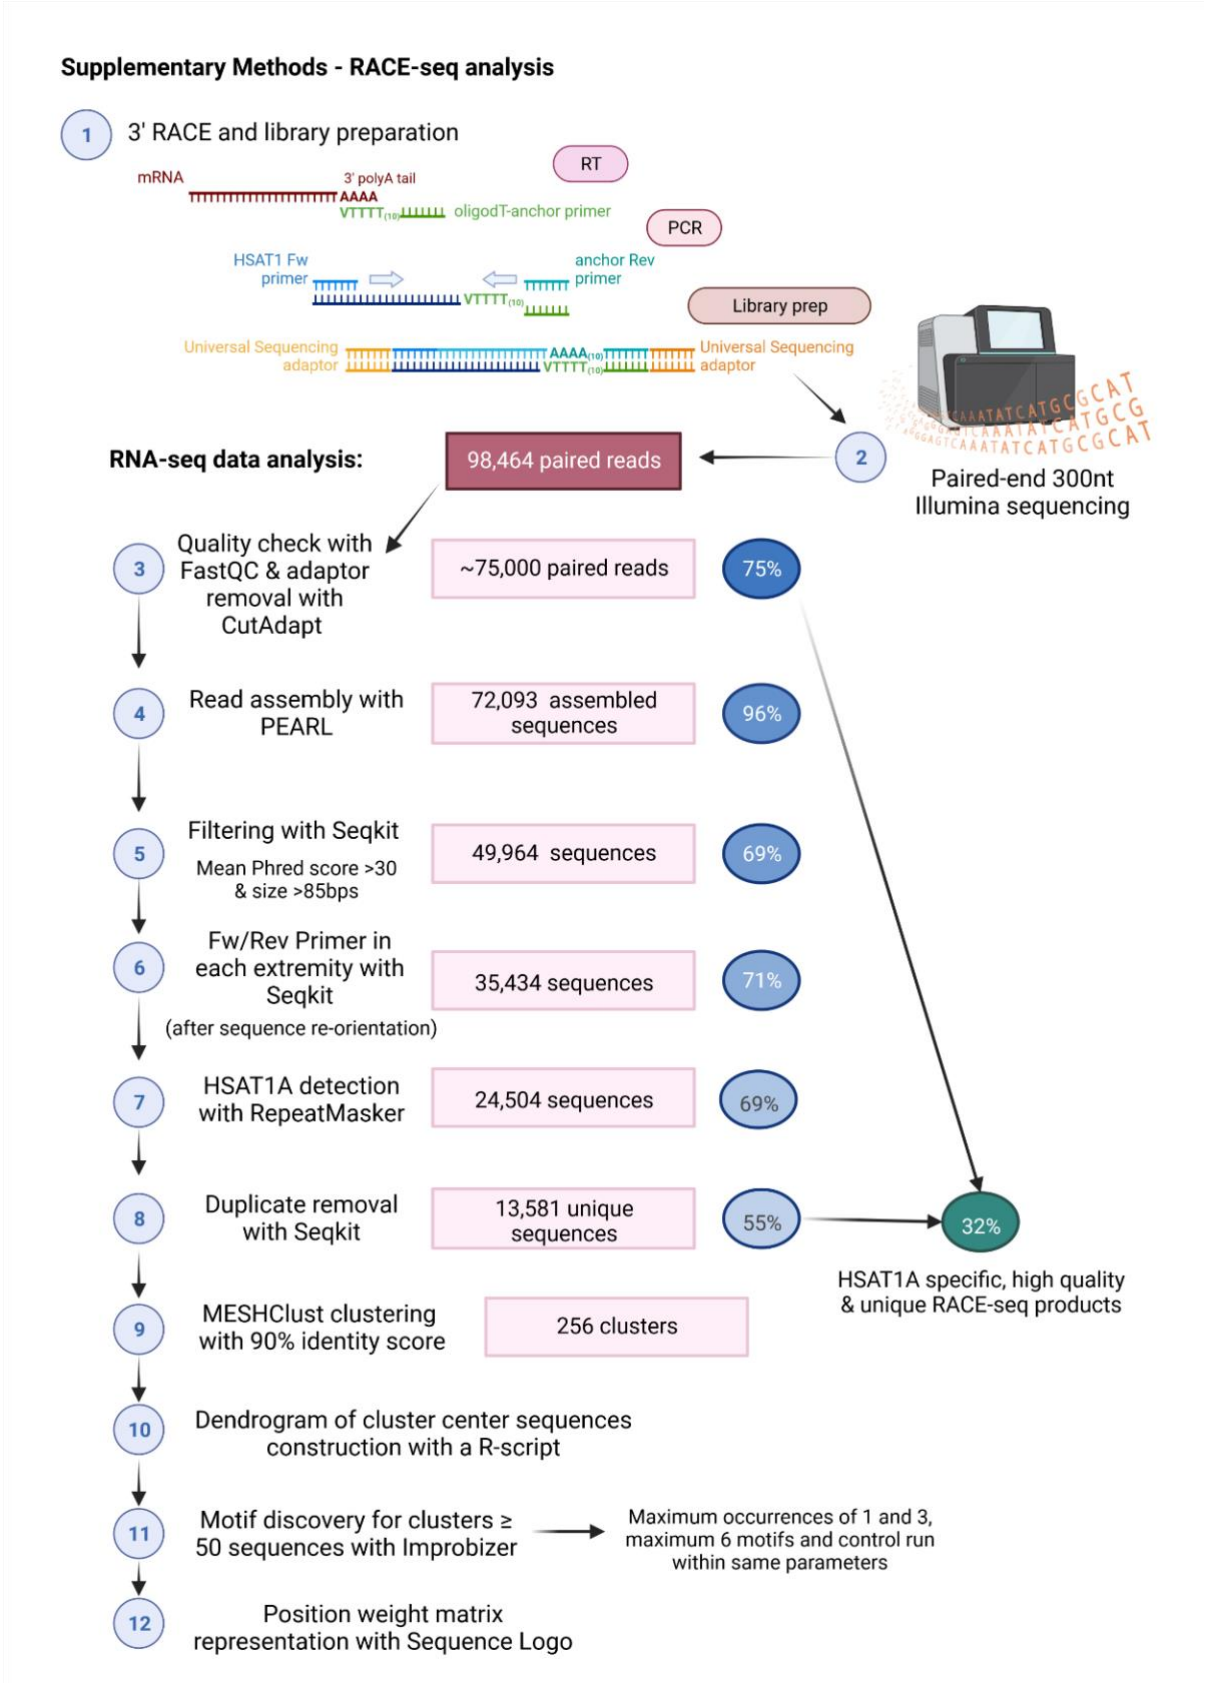

Figure 11 – Workflow for the analysis of HSat1A RACE-Seq.

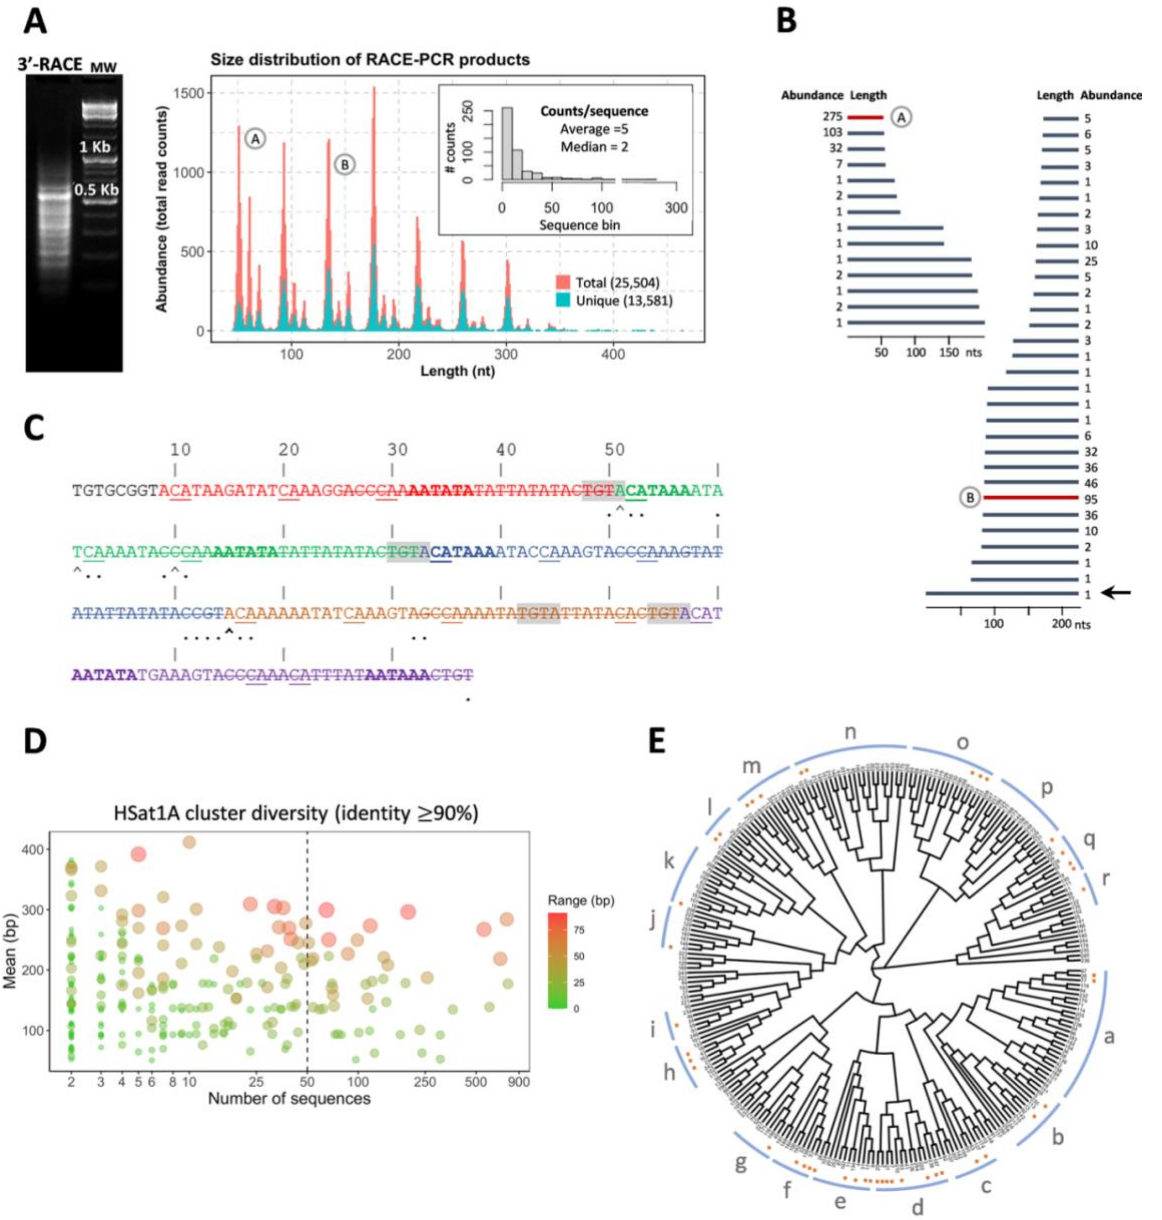

Figure 12 - HSat1A 3′ RACE analysis. A: Agarose gel corresponding to HSat1A 3′ RACE-amplified transcripts (left); Molecular weight (right). A size distribution plot is presented for the graphical representation of HSat1A reads. Assembled transcripts contained HSat1A peaks corresponding to multiples of the 42-monomer. From the total of HSat1A sequences, 16,332 sequences were found to be unique (blue in plot). The bar chart (top right corner) shows the high representation of unique sequences, visible in the distribution of counts/sequence. A and B (round) sequences are representative of the identified peaks and are displayed in B. **B**: HSat1A tandem transcript organization. In a universe of 200 nucleotides, it is possible to reconstruct transcripts of longer lengths with smaller sequences. The black arrow points to the longer represented read (structure explored in C). **C**: HSat1A read structure analyzed in the light of the consensus mammalian poly(A) signal. Different colors display HSat1A monomers: HSat1A are organized in alternative A (17 nt) and B (25 nt); strikethrough nucleotides in the figure. Sequences that may function as poly(A) signal hexamers (Hirose & Manley, 1998) are highlighted in bold. Shades of gray correspond to the sequence that functions as the recognition of the poly(A) signal in the absence of the canonical hexamer element [A(A/U)UAAA]. Nucleotides located at the site of optimal 3′ cleavage, named the poly(A) site, are underlined. Arrows point to the largest number of duplicates that are cleaved at that nucleotide position (bold for the largest most abundant). Dots represent the cleavage location of duplicates that contain a diference≥1 nucleotide from the previous sequence. The cleavage positions address the possible occurrence of alternative polyadenylation, resulting in the observable variation of transcript length. **D**: HSat1A transcript cluster membership. Colors determine the range (bp) between sequences of the same cluster. **E**: Phylogenetic tree depicting transcript variability, constructed from the multiple alignment between the center sequences of each cluster. Clusters can be grouped according to their distance (groups a–r). Orange dots represent clusters with more than 50 elements.

4. Discussion

4.1 PMSat as the most abundant satellite DNA of *Peromyscus genus*

This analysis showed that PMSat is the most abundant satDNA in the *Peromyscus* genus, consistent with previous studies (Louzada et al., 2015; Smalec et al., 2019). The abundance of this satDNA in the *Peromyscus genus* indicates a great importance of this sequence, that might be relevant in chromosome rearrangements that may drive speciation events, as it been shown on previous studies (Smalec et al., 2019). In accordance with Smalec et al. study it is possible to assert some similarities between the PMSat hybridization positioning and the sequence-based analysis performed in this work with subsequent relative positioning of PMSat arrays on chromosomes in four *Peromyscus* genus assemblies (PMAN, PCAL, PERE and PLEU). Some exceptions occur specifically in the PCAL assembly, as some PMSat arrays appear assembled near the end of multiple chromosomes in the sequence-based relative positioning, while in the PMSat hybridization this is not the case (Smalec et al., 2019). This may be derived by the presence of translocations within these regions of the chromosomes, or from misassembling of the chromosomes corresponding to this species. Notwithstanding, phylogenetic relation between the PMSat clustered groups from these four *Peromyscus* spp. seem to be in accordance with the phylogenetic tree assembled with previous studies performed with mitochondrial cytochrome-*b* sequences (Bradley et al., 2007) and PMSat hybridization data from *Peromyscus* spp. (Smalec et al., 2019). An important characteristic regarding the relative positioning of the PMSat arrays from each clustered group is the representativity on many different chromosomes across different assemblies, which could imply that translocations events between non-homologous chromosomes are frequent within species in this genus. This PMSat sequence clustering representation might also be an indication of molecular drive for speciation in this genus.

PMSat seemed to demonstrate common features across all genomes with similar monomer length, however, monomer and array GC-content, and array length showed variations among the genomes. A major common feature is that the monomer length seems to be ~345 bp, and that GC-content ranges from mainly 40-48%, which is correspondent with satellite DNA characteristics. The GC-content of both PMSat monomer and arrays showed slight variations among the genomes. The feature that showed a significant variation was the array length, which in some species showed a low range, such as the PMAN and PCAL, while the PERE and PLEU genomes showed a propensity for PMSat with higher array length.

Localization of LTRs within the four genomes selected showed important information regarding not only selective orientation, but also that series of ordered arrays may be maintained across their genomes. A good example of this would be in chromosome 13, that showed PMSat arrays detected across all genomes to be ordered in the minus strand, located mainly closest to the start of the chromosome. This type of behavior from LTR arrays could be relevant, given the instability associated with repetitive DNA sequences (Bzymek & Lovett, 2001; Vondrak et al., 2020). Furthermore, inspection of clustered groups of PMSat may also show important connections maintained based on similarity across all genomes. Such as the case of a specific cluster group that showed 2 similar arrays ordered together in chromosome 12 and in similar vicinity, detected in both the PMAN and PCAL assembly. This might indicate a strong connection of these

PMSat arrays between these two species, although their phylogenetic relationship showing greater distance when compared to other selected species, such as PLEU (Smalec et al., 2019).

4.2 LTR classes from the *Peromyscus* genus may have an important role across different genomes

The clustering analysis of LTR arrays within various *Peromyscus* genome assemblies has shed light on the diversity and distribution of these repetitive elements across species. The presence of highly similar LTR arrays across different species highlights the conservation of specific LTR classes within the *Peromyscus* genus. These findings might indicate a significant role of these LTRs in these genomes.

It is worth noting that the differences in the distribution of LTR classes across assemblies, as observed in this study, may reflect variations in genome assembly quality and sequencing methods, as these factors can impact the detection and annotation of repetitive elements (Treangen & Salzberg, 2012). Nevertheless, these differences might still be attributed to the evolutionary history of the *Peromyscus* genus (Harringmeyer & Hoekstra, 2022; Smalec et al., 2019).

Newly identified LTRs were found present across *Peromyscus* genus genomes. Of these new LTRs, the LTR_PMAN_1 and LTR_PMAN_2 classes have a higher count detection in comparison with other newly identified LTRs in the PCAL assembly. These classes also have a high copy number of monomers in their arrays, which might suggest a significant role of these newly identified LTRs in this species. However, both of these classes had no representativity shown on the chromosomes for relative positioning analysis, because they were only detected in scaffolds.

LTR classes LTR_PCAL_1, LTR_PCAL_2, LTR_PERE_10, LTR_PERE_14, and LTR_PLEU_4 although showing representativity on at least two assemblies from different species, only had between two or three copy number in their arrays. This may mean that these classes are correlated with transposable elements inserted on chromosomes in the ancestral of *Peromyscus* spp. Additionally, as shown in another study, these classes can also represent an important factor in the unique landscape of TEs of this genus in comparison to other mammalian genomes (Gozashti et al., 2023).

Newly identified LTR classes that showed similar characteristics but had more than three copy numbers in their arrays also had important characteristics to denote. The LTR_PMAN_5 class had arrays detected on chromosomes 11 and 15 in different species, which might be an indication of a translocation event. Furthermore, other newly identified LTR classes with these characteristics, such as LTR_PMAN_7 and LTR_PCAL_16, were only detected in the same chromosome between species (chromosomes 4 and 8, respectively). This might indicate a relevant role of these LTRs in their respective chromosomes. Some of these newly identified LTR classes were also located on distinct regions of chromosomes in different species, which could indicate the occurrence of crossing-over events of these LTRs.

From other satDNA families outside of PMSat it was also possible to determine some important interactions. The MMSAT4 family showed that a crossing-over event in chromosome 1 might have driven to a divergence between species seen between PERE and PLEU, which have been shown to be further apart phylogenetically (Bradley et al., 2007; Smalec et al., 2019). However, MurSatRep1 showed indication of a

crossover event of representative arrays on chromosome 6 that might separate PCAL from PMAN, PERE and PLEU, which goes against the phylogenetic distance between these four species.

Studying these LTR classes taking advantage of long contiguous reads, such as produced by nanopore sequencing technology, could provide further insight into specific arrangements from crossing-over events within the *Peromyscus* genus. Furthermore, it would also be of interest to study these LTR classes in additional *Peromyscus* spp., in order to obtain information regarding the chromosomal evolution and speciation events within this genus.

4.3 Diversity of human LTRs and HSAT1A transcription activity

Identifying and characterizing LTR arrays is difficult because due to their variable length and sequence they require long sequencing reads for their proper characterization. Although nanopore sequencing technology fixes this problem, this sequencing method was developed very recently and is still under constant improvement (Jain et al., 2018; Nurk et al., 2022). Several research efforts are underway to improve the identification and characterization of LTRs using a combination of sequencing technologies, developing new bioinformatics tools and algorithms, and making the technology more accessible and affordable, which can advance our understanding of LTRs (Altemose, 2022; Lopes et al., 2021; Miga, 2021). The results presented in this thesis can be seen as a part of this endeavor. For example, the DNA isolation and sequencing protocol used in this study showed improvement on the overall percentage of long reads compared to the publicly available NA12878 dataset for the same nanopore sequencing technology used. Nevertheless, there are still some challenges in the production of ultra-long reads.

The results obtained in this thesis suggest that there are significant differences in the NA12878 dataset in comparison with the GM03417 and CHM13 datasets, as it demonstrated a much lower percentage of clustered LTR groups. Additionally, detection of the most abundant satellite DNA, ALR, also showed a lower percentage of all the in the NA12878 sequencing data, although other satellite DNA did not show significant variation in percentages. This might be an indication of a higher fragmentation in the isolation of DNA for library preparation in this dataset. Nevertheless, it was possible to confirm the presence of the most common human satellite DNA in the top 20 clustered groups of LTRs on all assemblies, corresponding with previous characterization of satellite studies in the human genome (Altemose, 2022; Lopes et al., 2021).

Of note, the clustering analysis performed in this thesis identified some LTRs that had not been previously described in other studies, which were also present in the top 20 most abundant groups, specifically in the CHM13 Telomore-2-Telomere Consortium dataset (Altemose et al., 2022; Nurk et al., 2022). Although the number of these new arrays is lower than those of human satellite DNA, they could still represent significant repetitive element families with important functions.

Regarding the use of flow cytometry-based isolation for sequencing of individual chromosomes, it seems to be a valuable approach for studying chromosomal abnormalities such as translocations, as it was successful in isolating the translocated chromosome rob(14:21) along with other chromosomes. This is in line with a previous study using this approach (Kuderna et al., 2019). However, the results indicate that this method might not be efficient for the study of repetitive sequences, as the length of the reads produced suggested significant DNA fragmentation before library preparation.

Finally, with the use of 3' RACE to characterize HSat1A transcripts, it was possible to verify that the size variability of HSat1A transcripts is most likely associated to alternative polyadenylation (APA), which can be regulated by various factors, including a fundamental co-transcriptional gene regulation process that relies on U1 small nuclear ribonucleoprotein (snRNP) to suppress premature 3'-end cleavage and polyadenylation (PCPA) in RNA polymerase II transcripts, which is necessary for full-length transcription of thousands of protein-coding (pre-mRNAs) and long noncoding (lncRNA) genes (a process called U1 telescripting), and non-canonical polyadenylation signals (Cugusi et al., 2022). The accumulation of HSat1A transcripts is thought to be dependent on a complex interplay between transcriptional and post-transcriptional processes (Eymery et al., 2009). It is also of note that abnormal transcription of satellite sequences is a common feature of tumor cells (Eymery et al., 2009; Puppo et al., 2020), suggesting that further functional studies are needed to determine the role of HSat1A in genome architecture, gene expression regulation, and cellular pathways involved in stress, development, and pathology. To better understand the function of HSat1A, performing experiments to knock down the transcript and evaluate the resulting cellular phenotypes is recommended. Additionally, investigating the pathways that regulate the expression of HSat1A transcripts is crucial for understanding their role in tumor development. Exploring HSat1A transcripts could provide valuable information about the mechanisms underlying abnormal transcription in tumor cells and their involvement in disease development.

4.4 Concluding remarks

This work demonstrated the ability to detect and assess LTRs using different sequencing methods. The study of LTRs on *Peromyscus* spp. showed interesting patterns and relationships that allowed for a better characterization of these previously and newly identified LTR classes. The relative positioning of the most abundant satDNA family on *Peromyscus* genus, PMSat, with other LTR classes also allowed for a better depiction of these repetitive elements.

Nanopore sequencing technology showed great potential for a better quantification and characterization of LTRs in the human genome. However, some challenges in identifying and characterizing LTRs using this sequencing technology simultaneously with flow-sorting of chromosomes were acknowledged, and resolutions to improve these methods were highlighted. Some novel LTRs were also identified in the human genome. Furthermore, the characterization of the HSat1A family revealed not only to be transcriptionally active, but also that a high degree of variability between genomic and transcriptomic sequences.

Overall, this analysis contributed to a better characterization of LTRs, with implications in genomic organization and evolution. Notwithstanding, further investigation and functional studies are of great importance to elucidate the specific functions and mechanisms of these repetitive elements.

6. Supplementary Data

Supplementary Table 1 – Clustering of LTRs detected in the PMAN 1.0 assembly.

Cluster Group	Arrays	min size (bp)	mean size (bp)	max size (bp)	Type	Repeat
1	870	340	357.6	1436	Satellite	PMSAT
2	11	69	70.1	73	Unclassified	LTR_PMAN_1
3	4	1648	1702	1781	TE	L1_Mur2_orf2
4	4	93	140	234	Unclassified	LTR_PMAN_2
5	4	83	84	85	Satellite	MurSatRep1
6	4	84	84	84	Satellite	MurSatRep1
7	3	1201	1528.7	1860	TE	L1_Mur2_orf2
8	3	70	105	141	TE	B1_Mus1/2
9	3	77	77	77	Unclassified	LTR_PMAN_3
10	2	1399	1408.5	1418	Unclassified	LTR_PMAN_8
11	2	1031	1111	1191	Unclassified	LTR_PMAN_9
12	2	803	937.5	1072	TE	RMER1C
13	2	993	999.5	1006	Unclassified	LTR_PMAN_10
14	2	499	500	501	Unclassified	LTR_PMAN_11
15	2	84	84	84	Satellite	MMSAT4
16	2	72	72	72	Unclassified	LTR_PMAN_4
17	2	63	63	63	Unclassified	LTR_PMAN_5

Supplementary Table 2 – Clustering of LTRs detected in the PMAN 2.1 CONTIGS assembly.

Cluster Group	Arrays	min size (bp)	mean size (bp)	max size (bp)	Type	Repeat
1	698	323	344	349	Satellite	PMSAT
2	8	68	70.1	73	Unclassified	LTR_PMAN_1
3	7	682	760.9	1223	Satellite	PMSAT
4	3	93	108.3	139	Unclassified	LTR_PMAN_2
5	3	84	84.3	85	Satellite	MurSatRep1
6	3	84	84	84	Satellite	MurSatRep1
7	3	77	77	77	Unclassified	LTR_PMAN_3
8	2	243	243	243	TE	B1_Mus1
9	2	70	87	104	TE	B1_Mus1
10	2	95	95	95	Unclassified	LTR_PMAN_6
11	2	84	84	84	Satellite	MMSAT4
12	2	72	72	72	Unclassified	LTR_PMAN_4
13	2	69	69	69	Unclassified	LTR_PMAN_7

14	2	63	63	63	Unclassified	LTR_PMAN_5

Supplementary Table 3 – Clustering of LTRs detected in the PMAN 2.1 CHR assembly.

Cluster Group	Arrays	min size (bp)	mean size (bp)	max size (bp)	Type	Repeat
1	657	323	344	349	Satellite	PMSAT
2	8	1340	1702.9	1969	TE	L1_Mur2_orf2
3	8	68	70.1	73	Unclassified	LTR_PMAN_1
4	7	682	743.1	1095	Satellite	PMSAT
5	4	84	84.2	85	Satellite	MurSatRep1
6	3	93	108.3	139	Unclassified	LTR_PMAN_2
7	3	84	84	84	Satellite	MurSatRep1
8	3	77	77	77	Unclassified	LTR_PMAN_3
9	2	1706	1828	1950	TE	L1_Mur3_orf2
10	2	790	802.5	815	TE	RMER1C
11	2	243	243	243	TE	B1_Mus1
12	2	70	87	104	TE	B1_Mus1
13	2	84	84	84	Satellite	MMSAT4
14	2	72	72	72	Unclassified	LTR_PMAN_4

Supplementary Table 4 – Clustering of LTRs detected in the PCAL assembly.

Cluster Group	Arrays	min size (bp)	mean size (bp)	max size (bp)	Type	Repeat
1	467	333	344.5	350	Satellite	PMSAT
2	310	67	75.9	206	Unclassified	LTR_PMAN_1

Supplementary Table 10 – Distribution of PMSat arrays on chromosomes across the four *Peromyscus* genomes. * The joint total of arrays calculated for chromosome 8 was done with both chromosomes 8a and 8b together (0+3+0+5+1), and 16 and 21 was done with chromosome 16_21 for each (chr16: 0+5+1+1; chr21: 5+4+8+1).

Supplementary Table 11 – Clustered groups of PMSat based on identity score threshold of 0.9. PMSat monomers from each array were clustered based on their identity score with MeShClust v3.0 (Girgis, 2022). The letters on column 'C/M/E' represent the classification within the clustered group: C – Center (identity score ≈ 1); M – Member (0.9 < identity score < 1); E – Extended Member (identity score < 0.9).

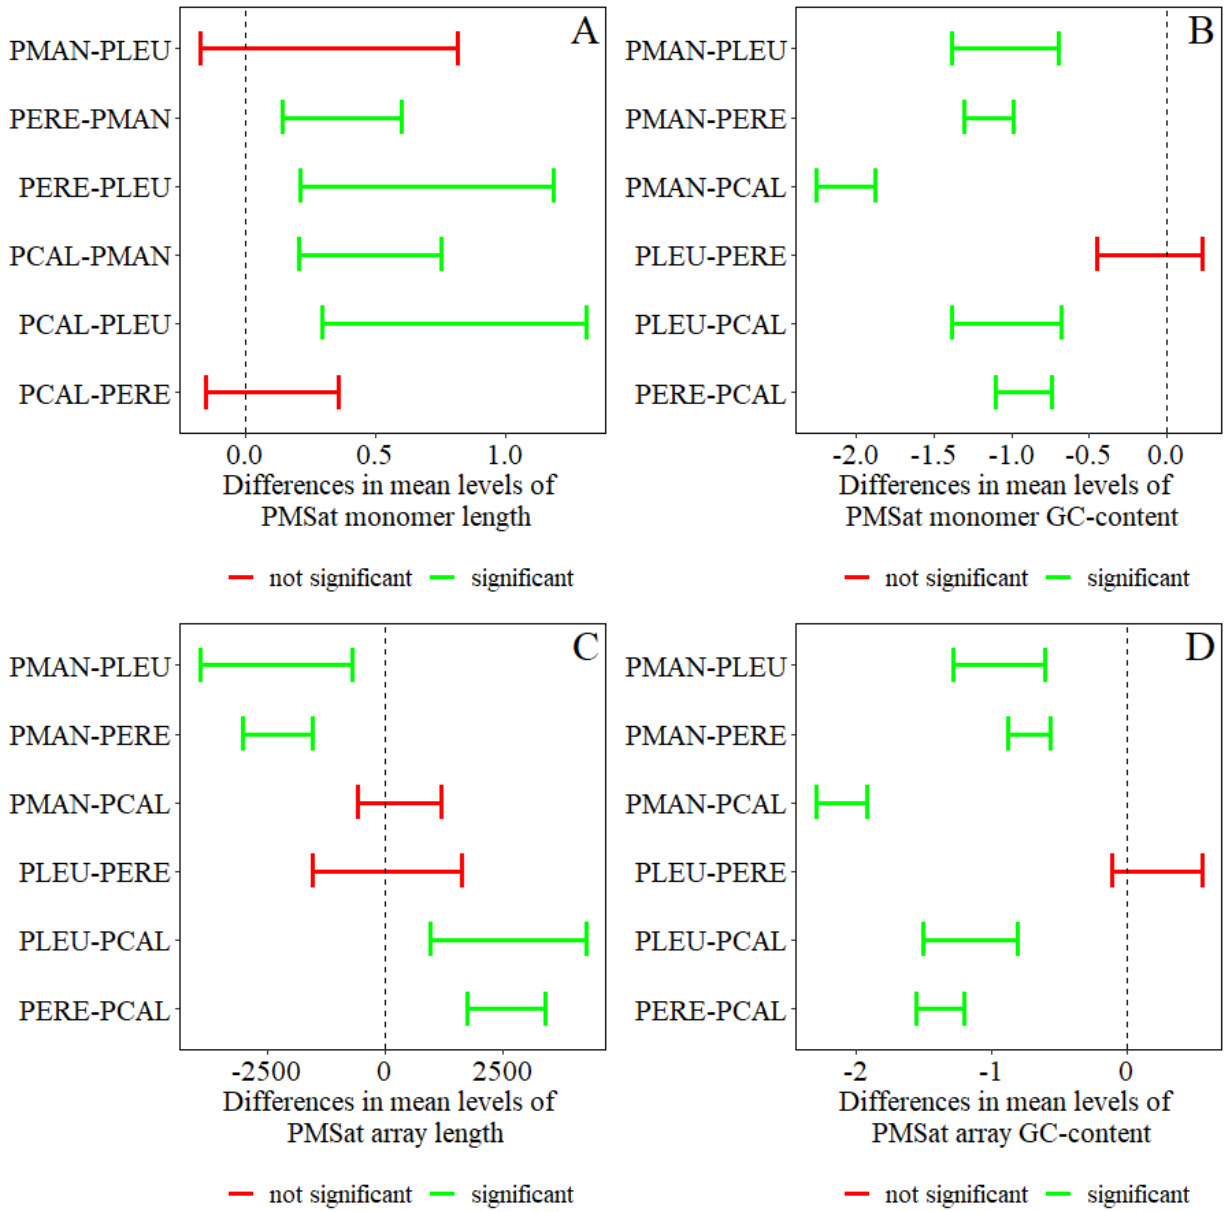
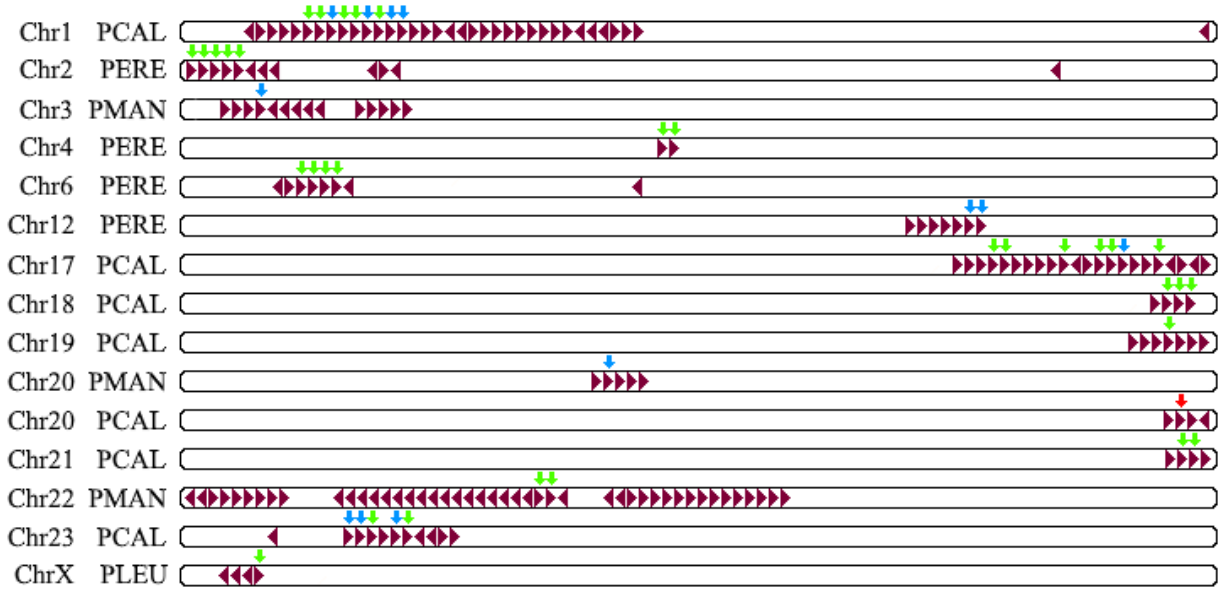
Supplementary Table 15 – Sequencing run of 3'RACE-Seq. Quantification of number of bases and reads, with mean read length (Whole Genome Library Preparation, Illumina MiSeq plataform, NGS Sequencing service STAB VIDA).

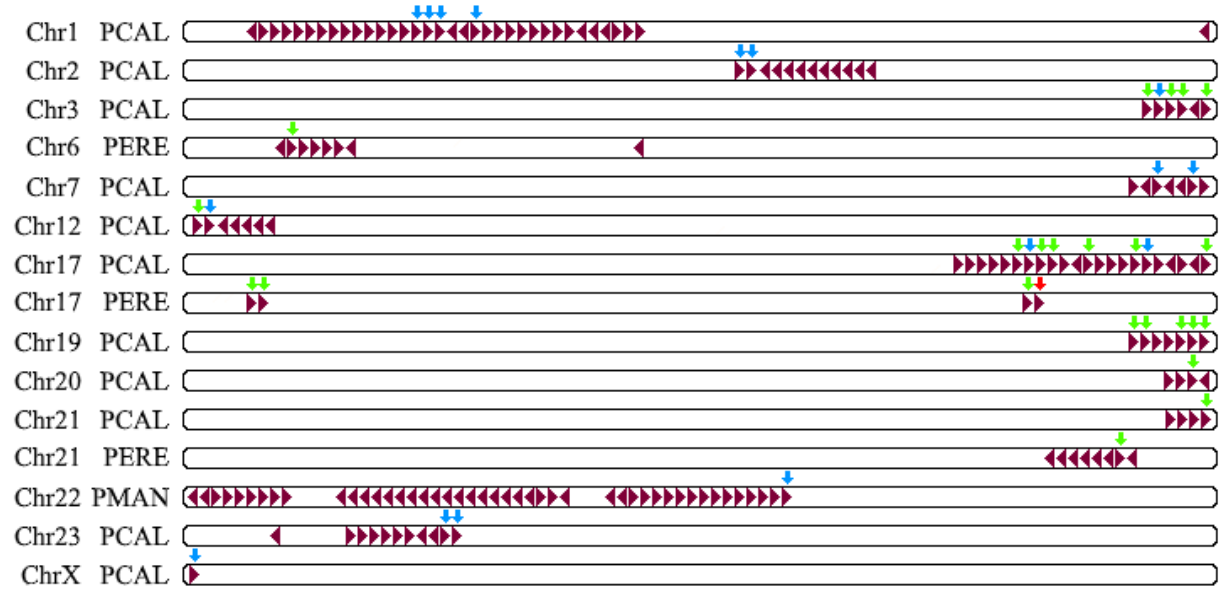
Number Of Bases (Raw Data) [Mbp]	Number Of Reads (Raw Data)	Mean Read Length [bp]
59.27	196,928	300



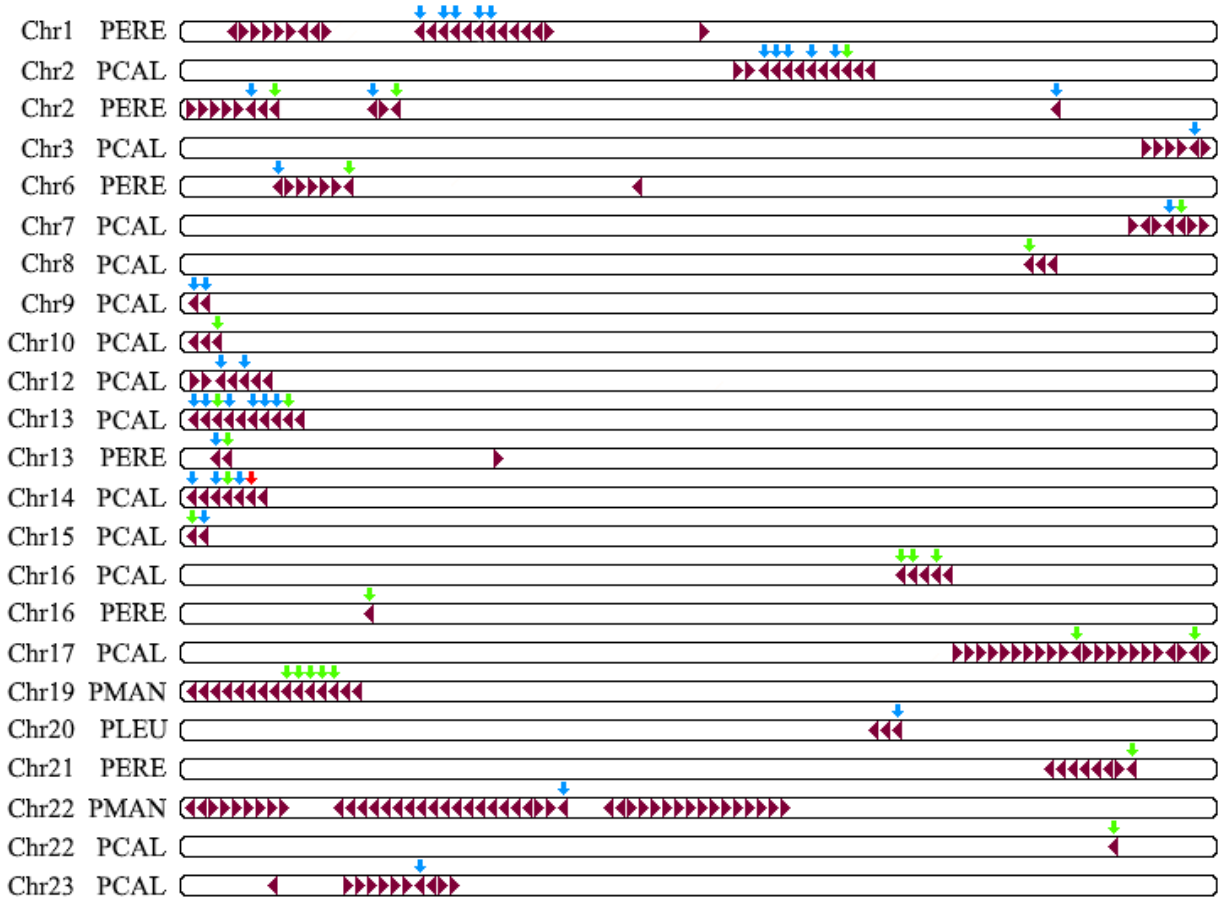
Supplementary Figure 1 – Tukey Post-Hoc test of differences in mean levels of PMSat monomer length (A), monomer GC-content (B), array length (C) and array GC-content (D) across the four Peromyscus species. The significant groupwise differences are anywhere the 95% confidence interval doesn't include zero ($p < 0.05$).



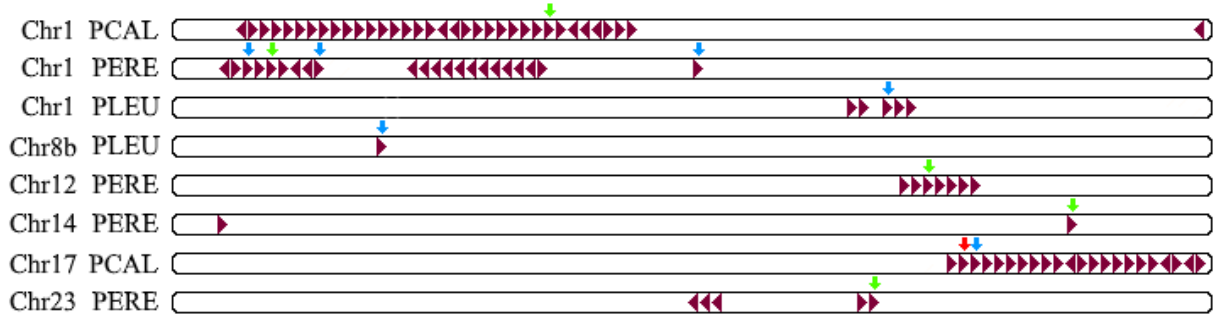
Supplementary Figure 2 - Orientation and relative localization of cluster group 2 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).



Supplementary Figure 3 – Orientation and relative localization of cluster group 3 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

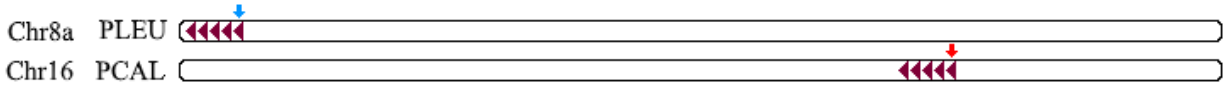


Supplementary Figure 4 – Orientation and relative localization of cluster group 4 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

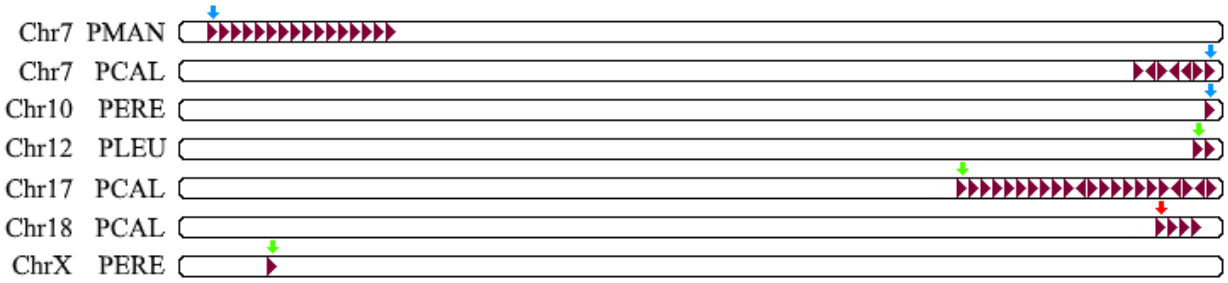


Supplementary Figure 5 – Orientation and relative localization of cluster group 5 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

Supplementary Figure 6 – Orientation and relative localization of cluster group 6 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).



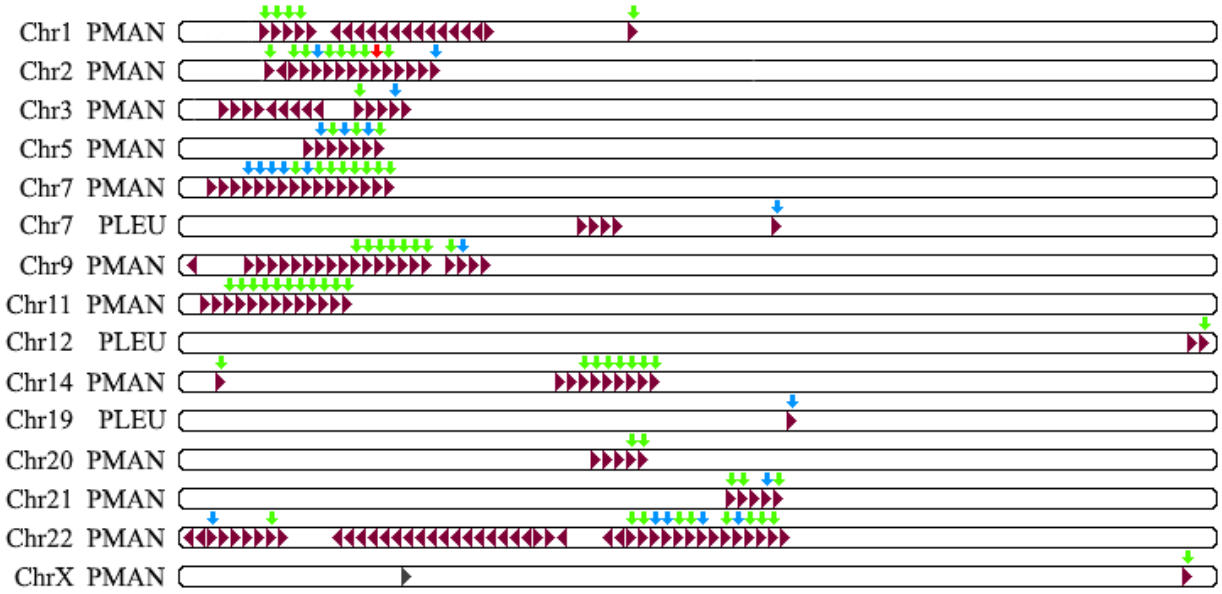
Supplementary Figure 7 – Orientation and relative localization of cluster group 7 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).



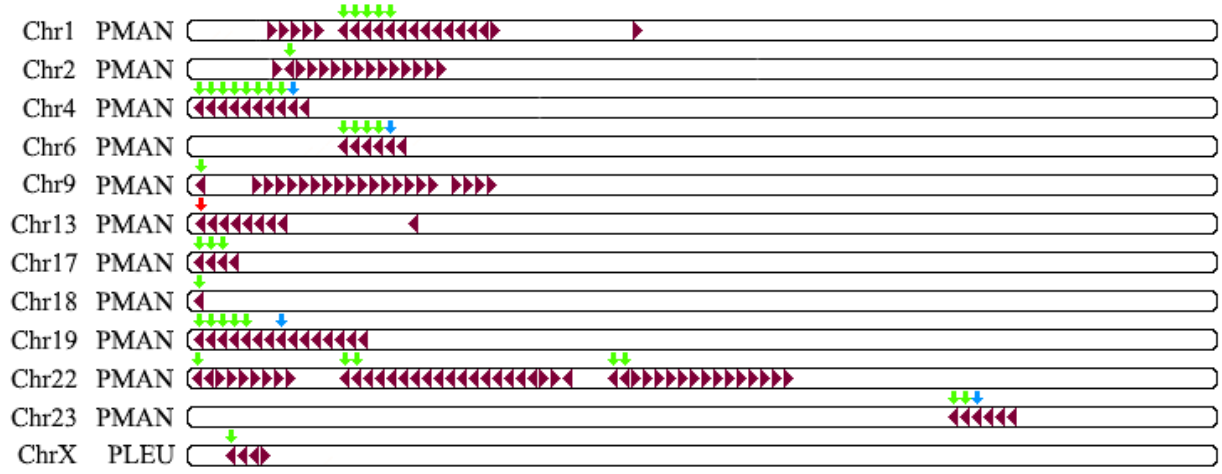
Supplementary Figure 8 – Orientation and relative localization of cluster group 8 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

Supplementary Figure 9 – Orientation and relative localization of cluster group 9 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

Supplementary Figure 10 – Orientation and relative localization of cluster group 10 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

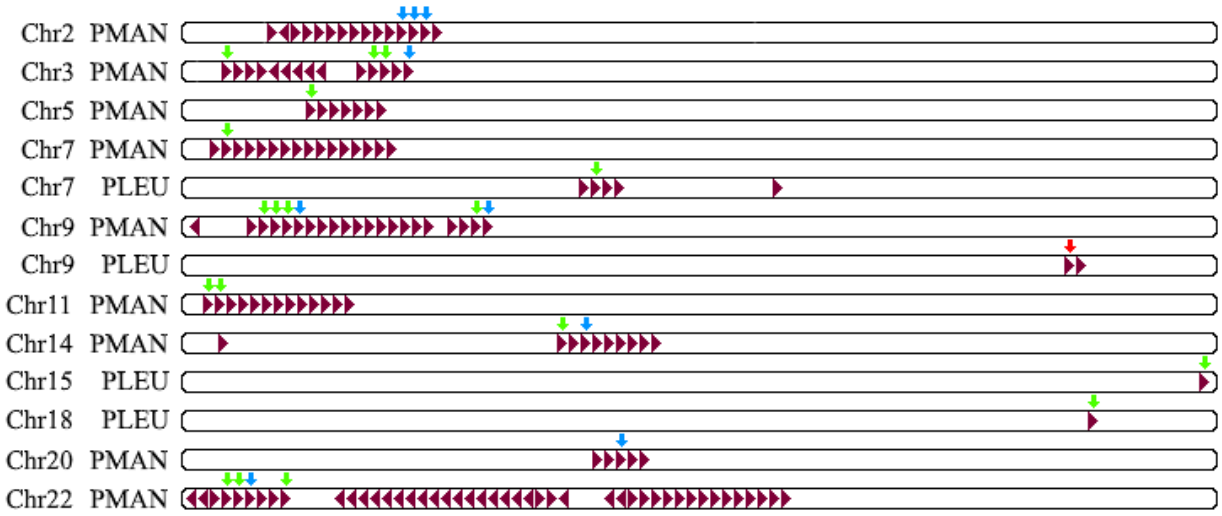


Supplementary Figure 11 – Orientation and relative localization of cluster group 11 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).



Supplementary Figure 12 – Orientation and relative localization of cluster group 12 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

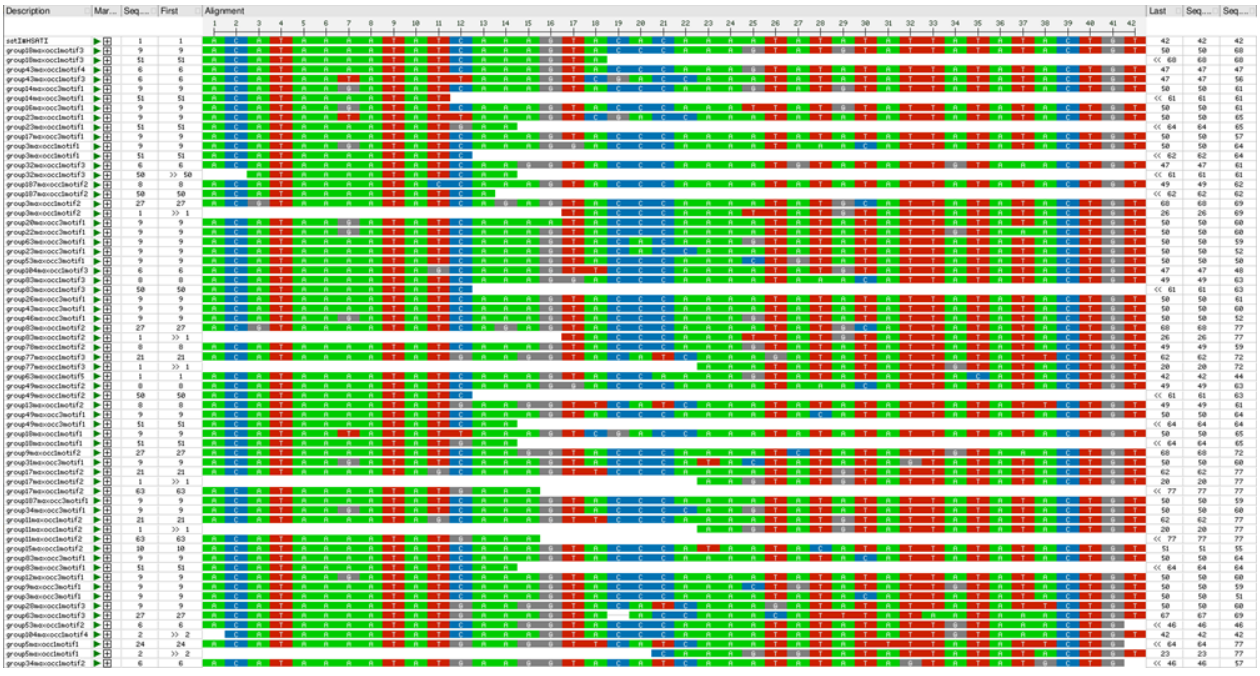
Supplementary Figure 13 – Orientation and relative localization of cluster group 13 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).



Supplementary Figure 14 – Orientation and relative localization of cluster group 14 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

Supplementary Figure 15 – Orientation and relative localization of cluster group 15 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).

Supplementary Figure 16 – Orientation and relative localization of cluster group 16 of PMSat arrays based on identity score threshold of 0.9. These arrays are represented on the chromosomes matching each *Peromyscus* genome assembly. Each PMSat array was placed based on the relative position of the coordinates of where it was detected. The arrows represent the classification within the clustered group, based on their identity score from MeShClust v3.0 (Girgis, 2022) clustering: Red – Center (identity score ≈ 1); Green – Member (0.9 < identity score < 1); Blue – Extended Member (identity score < 0.9).



Supplementary Figure 17 - Comparison between the HSat1A monomer sequence and a selection of motifs sequences in each cluster group through a merged alignment.
